COULSON, WILLIAM, Engineer in charge of Workshops, The Electrical Installation & Repairing Co., 40 Berry St., Belfast, Irelnda.

CRAGO, PAUL HUGHES, Electrical Engineer, Union Switch & Signal Co., Swissvale; res., Forest Hills Boro, Wilkinsburg, Pa.

CRAVEN, FRANK ELMER, Engineering Assistant, Bell Telephone Co. of Pa., 261 N. Broad St., Philadelphia, Pa.

CRAWFORD, JAMES M., Asst. General Foreman, Testing Dept., General Electric Co., Schenectady, N. Y.

CROCK, ISRAEL Z., Specification Engineer, New England Tel. & Tel. Co., 50 Oliver St., Boston, Mass.

CROWELL, RALPH MILTON, Operator, Utah Power & Light Co., 133 S. West Temple, Salt Lake City, Utah.

CRUMP, LEONARD WADE, Draftsman, Puget Sound Power & Light Co., 1306 A St., Tacoma, Wash.

*CURTIS, GEORGE V., Testing Dept., General Electric Co., Schenectady, N. Y.

CUTHBERT, JAMES TAYLOR, Chief Electrician, Duquesne Light Co., Pittsburgh, Pa.

DAMON, ALFRED C., Test Dept., Simplex Wire & Cable Co., 66 Sidney St., Cambridge; res., Cochituate, Mass.

DAUGHERTY, THOMAS CLARKE, Telephone Traffic Engineer, New England Tel. & Tel. Co., 50 Oliver St., Boston, Mass.

DAVIS, JOHN CASSIUS, Jr., Trouble Dispatcher, Edison Electric Illuminating Co., 1165 Massachusetts Ave., Roxbury; res., Dorchester, Mass.

DAVIS, WILLIAM, Asst. Engineer, Toronto Hydro-Electric System, Toronto, Ont., Can.

DAVISON, CHARLES, Land Line Inspector, Mexican Telegraph Co., Calle de Escandon No. 99, Orizaba, Vera Cruz, Mexico.

DAY, WILLIAM POWELL, Head, Turbine Test Dept., General Electric Co., Schenectady, N. Y.

DEAN, CHARLES PHILIP, Laboratory Supervising Engineer, Bell Telephone Laboratories, Inc., 463 West St., New York, N. Y.; res., Summit, N. J.

DE CELIS, FRANCISCO, High Tension Inspector of Meters, Mexican Light & Power Co., Mexico City, Mex.

DEDEK, FRANK G., Asst., Electrical Laboratory, Burroughs Adding Machine Co., Second Blvd., Detroit, Mich.

DELLINGER, FLOYD ELLIOTT, Overhead Electrical Engineer, Los Angeles Gas & Electric Corp., 810 S. Flower St., Los Angeles, Calif.

DENEEN, ROBERT J., Dist. Sales Manager, Ohio Brass Co., 1714 Fisher Bldg., Chicago, Ill.

DENNIS, WILLIAM EDWIN, Asst. Electrical Engineer, Bombay Baroda & Central India Railway, Church Gate St., Bombay, India.

DERRONE, MARCEL, Electrical Engineer, S. F. de M. D'e. A. Tekka, Gopeng, Perak, F. M. S.

DE VRIES, BERNARD E., Electrical Engineer, Engg. Dept., Duquesne Light Co., Duquesne Bldg., Pittsburgh, Pa.

DICKERSON, FRANCIS ARTHUR, Asst. Engineer, New York Telephone Co., 104 Broad St., New York.; res., Brooklyn, N. Y.
DIEHL, WILLIAM ARTHUR, Asst. Maintenance Engineer, National Malleable & Steel Castings Co., Cleveland, Ohio.
DOANE, PHILIP, Electrical Tester, New York Edison Co., 92 Vandam St., New York; res., Brooklyn, N. Y.
DODDS, VINCENT G., Local Manager, Aluminum Co. of America, 100 State St., Albany, N. Y.
DOWE, GEORGE PHILLIPSON, Draftsman, The Canadian Crocker-Wheeler Co., St. Catharines, Ont., Can.
*DREYFUS, JAMES, Equipment Engineer, New York Tel. Co., 360 Bridge St., Brooklyn, N. Y.
DRING, LOUIS GABRIEL, Telephone Inside Man, New York Telephone Co., 15 Dey St., New York, N. Y.
DUEVEL, CHARLES OTTO, Jr., Heating & Ventilating Engineer, Consumers Central Heating Co., 108 E. 11th St., Tacoma, Wash.
DUFFY, LEE, Substation Operator, Puget Sound Power & Light Co., 1428 Boylston Ave., Seattle, Wash.
DUNHAM, DAVID, Engineer, Southland Electric Power Board, Invercargill; res., Gore, N. Z.
EBERHARDT, PAUL WILLIAM, General Safety Inspector, Duquesne Light Co., 435 6th Ave., Pittsburgh, Pa.
EDWARD, JOHN ANDREW, Hydro-Electric Power Station, Snoqualmie, Wash.
EHRKE, ERNEST BORMAN, Outside Salesman, Pacific States Electric Co., 236 S. Los Angeles St., Los Angeles, Calif.
ELLIS, DONALD WAYNE, Chief Electrician, Beech Bottom Power Co., Power, West Va.
ERICKSON, ELLIS O., Engineer, Supply Engg. Dept., Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa.
EVELAND, GEORGE HARMON, Engineer, Feather River Power Co., Hobart Bldg., San Francisco, Calif.
EWING, CHARLES, Electrical Engineer, Louisville Gas & Electric Co., 311 W. Chestnut St., Louisville, Ky.
FAGAN, HENRY JOSEPH, 1555 Walton Ave., Bronx, New York, N. Y.
FALK, VICTOR EMANUEL, Electrical Designer, Stone & Webster, Inc., 147 Milk St., Boston, Mass.
FALOR, HAROLD LEROY, Chief Operator, Northern Ohio Power & Light Co., Terminal Bldg., Akron, Ohio.
FAUERBACH, WALTER FREDERICK, Salesman, Westinghouse Elec. & Mfg. Co., 150 Broadway, New York; res., Hollis, N. Y.
*FAWCETT, O. EMMETT, Asst. Electrical Engineer, West Penn Power Co., 14 Wood St., Pittsburgh, Pa.
FEINDEL, ABBOTT, Cable Tester, New York Edison Co., 708 1st Ave., New York; res., Brooklyn, N. Y.
FLORY, CARL LEONARD, Asst. Engineer in charge, Radio Corp. of America, Tuckerton, N. J.
FONTAINE, JAMES, Research Assistant, Engineering Experimental Station, North Carolina State College, Raleigh, N. C.
FORSYTH, JOSEPH WILSON, Engineer, City of Philadelphia, 6000 Rising Sun Ave., Philadelphia, Pa.
FREE, JOHN E., Supt., Electric Construction, General Electric Co., Witherspoon Bldg., Philadelphia, Pa.
*FRENCH, MURVIN ARVILLE, Inspector, Underground Cable Construction Dept., Chas. H. Tenney & Co., 200 Devonshire St., Boston; res., Framingham, Mass.
FUHS, RAYMOND H., Electrical Engineer, Indianapolis Light & Heat Co., 48 Monument Place, Indianapolis, Ind.
GALE, ARTHUR P., Director of Public Relations, Wisconsin Power & Light Co., 900 Gay Bldg., Madison, Wis.
GAMBITTA, A. FILADELFIO, Research Work, 6 W. 28th St., New York, N. Y.
GANTENBEIN, E. F., General Foreman, Line Dept., Puget Sound Power & Light Co., 601 Capitol Way, Olympia, Wash.
GARNER, FRED E., Dist. Sales Manager, Daven Radio Corp., 158 Summit St., Newark, N. J.
GARNETT, HARRY SEYS, Asst. Engineer, Messrs. Merz & McLellan, 32 Victoria St., Westminster, London, Eng.
GARRETSON, FRANCIS MARION, Jr., Research Engineer, Cooper Hewitt Electric Co., 95 River St., Hoboken; res., East Orange, N. J.
GAUCHET, CLIFFORD EDWARD, Street Lighting Specialist, General Electric Co., Pierce Bldg., St. Louis, Mo.
GHEN, MELVILLE W., Supervisor of Underground Construction, Duquesne Light Co., 800 Duquesne Bldg., Pittsburgh, Pa.
GIANGRANDE, DOMENIC MICHAEL, Draftsman, The New York Edison Co., 130 E. 15th St., New York, N. Y.
GIBNEY, EUGENE L., Draftsman, Lighting Dept., City of Seattle, 514 Prefontaine Bldg., Seattle, Wash.
GIBSON, FOSTER COLLINS, Dist. Manager, Edison Storage Battery Co., 509 Polson Bldg., Seattle, Wash.
GILLIS, MELVIN D., Foreman of Electrical Test, General Electric Co., Erie, Pa.
GILSON, WALTER JAY, Designing Engineer, Canadian & General Finance Co., 357 Bay St., Toronto, Ont., Can.
GOARD, LAMAR C., Distribution Supt., The Ohio Public Service Co., Ashland, Ohio.
GOYNE, THOMAS STUART, Sales Engineer, Goyne Steam Pump Co., Ashland, Pa.
GRANT, ALEXANDER JAMES, Electrical Engineer, Westinghouse Elec. & Mfg. Co., East Pittsburgh; res., Pittsburgh, Pa.
GRAUL, EDGAR ALBERT, Technical Clerk, Vice-President's Office, Duquesne Light Co., 300 Philadelphia Bldg., Pittsburgh, Pa.
GRAY, JOSEPH WILLIAM, Professor of Elec. Engg., Ohio Northern University, Ada, Ohio.
GREENE, EDWIN M., Draftsman, Engg. Dept., Commonwealth Edison Co., 72 W. Adams St., Chicago, Ill.
GREENE, J. H., Sanderson & Porter, 52 William St., New York, N. Y.
GRIFFIN, GEORGE HENRY, Student, Union Carbide Co., Saulte Ste Marie, Mich.
HADLEY, GEORGE F., Process Engineer, Westinghouse Elec. & Mfg. Co. East Pittsburgh; res., Pittsburgh, Pa.
HAERTLEIN, ALBERT, Supt., Plans & Schedules Div., Duquesne Light Co., 435 6th Ave., Pittsburgh, Pa.
*HANSEN, TED A., Automatic Substation Inspector, Puget Sound Power & Light Co., Electric Bldg., Seattle, Wash.
HARKINS, PERCY STONER, Division Plant Engineer, Bell Telephone Co. of Pa., 1230 Arch St., Philadelphia, Pa.
*HARNETT, DANIEL EDWARD, Electrical Engineer, Pacent Electric Co., 91 7th Ave., New York, N. Y.
*HARRELL, FREDERICK EDMUND, Sales Engineer, Reliance Electric & Engineering Co., 1088 Ivanhoe Road, Cleveland, Ohio.
HARTLE, WILBERT GRAY, Student Engineer, Testing Dept., General Electric Co., Schenectady, N. Y.
HARTRANFT, ARMAND C., Load Dispatcher, Philadelphia Electric Co., 1000 Chestnut St., Philadelphia; res., Germantown, Philadelphia, Pa.
HASKENS, ALBERT JACOB, Draftsman, Union Switch & Signal Co., Swissvale, Pa.
*HEFFELMAN, MALCOLM C., Electrician Foreman, Chile Exploration Co., Chuquicamata, Chile, S. A.
HELANDER, WALTER NATHANIEL, Meter Dept., Puget Sound Power & Light Co., 601 Capitol Way, Olympia, Wash.
HENDERSON, CHARLES L., Asst. Supt., Sub-Sta. Operation, West Penn Power Co., 14 Wood St., Pittsburgh, Pa.
HENDERSON, EUGENE WAYNE, Chief Electrician, Colfax Plant, Duquesne Light Co., Cheswick, Pa.
HERRERA, RAFAEL O., Student Engineer, General Electric Co., Schenectady, N. Y.
HILLOCK, JAMES FRANCIS, Senior Engineer, Customer's Section Duquesne Light Co., Duquesne Bldg., Pittsburgh, Pa.
HILTEBEITEL, JESSE, Chief Engineer, H. N. Crowder, Jr., Co., 446 Union St., Allentown, Pa.; res., New York, N. Y.
HITE, JOHN W., Electrical Inspector, Reliance Electric & Engineering Co., 1088 Ivanhoe Road, Cleveland, Ohio.
HOEFFLIN, ALBERT S., Elect. Operating Dept., Louisville Gas & Electric Co., 311 W. Chestnut St., Louisville, Ky.
HOEHN, EDUARD H., Junior Engineer, Union Electric Light & Power Co., 315 N. 12th Blvd., St. Louis, Mo.
HOULE, ARTHUR VICTOR, Tester, The New York Edison Co., 92 Vandam St., New York; res., Brooklyn, N. Y.
*HUBBARD, HENRY H., Engineering Assistant, Brooklyn Edison Co., 380 Pearl St., Brooklyn, N. Y.
HULTS, JOHN LAWRENCE, Engineer, Engg. Dept., The Ohio Public Service Co., Warren, Ohio.
HUMPHREYS, DAVID, Hydro-Elec. Supt. Engineer, Newfoundland Power & Paper Co., Ltd., Deer Lake, Newfoundland.
HURLBUT, WARREN O., Elec. & Mech. Engg. & Maintenance, Gas & Electric Service Co., 741 Broadway, Chico, Calif.
HYAMS, LEONARD BENJAMIN, Gothem Electric & Supply Co., 3416 Broadway, New York, N. Y.
HYLE, LEWIS CALUIN, Emaus Telephone Co., Emaus, Pa.
ISHIKAWA, KIYOSHI, Electrical Engineer, Shibaura Engineering Works, Tokio, Japan; International General Electric Co., Schenectady, N. Y.
JARVIS, MARTIN MICHAEL, Electrical Laboratory, Burroughs Adding Machine, Second Blvd., Detroit, Mich.
JIMENEZ, RUDOLPHO, Student Engineer, General Electric Co., Bldg. 41, Schenectady, N. Y.
JOHNSON, EDWARD LEONARD, Salesman, H. B. Squires Co., 552 1st Ave., S., Seattle, Wash.
JOHNSON, R. H., Draftsman, Puget Sound Power & Light Co., Bremerton, Wash.
*JOHNSON, ROBERT RAYMOND, Electrical Engineer, Engg. Dept., Duquesne Light Co., Pittsburgh, Pa.
JOHNSON, WILL M., Electrician, Portland Electric Power Co., Hawthorne Bldg., Portland, Ore.
JUDGE, FRED GEORGE, Sales Engineer, Pierce Electric Co., 206 S. Franklin, Tampa, Fla.
JUDY, EDWARD WINFIELD, General Supt. of Distribution, Duquesne Light Co., Duquesne Bldg., Cecil Way, Pittsburgh, Pa.
KANE, MARTIN P., Industrial Dept., Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa.
KELLERS, CHARLES FREDERICK, Testing Dept., General Electric Co., Schenectady, N. Y.
KEPPLE, KENNETH AUSTIN, Draftsman-Engineer, Westinghouse Elec. & Mfg. Co., East Pittsburgh; res., Jeannette, Pa.
KILBURY, WALTER ASA, Switchboard Operator, Cleveland Electric Illuminating Co., 313 Illuminating Bldg., Cleveland; res., Lakewood, Ohio.
KINCAID, MORLEY BERT, Draftsman, Westinghouse Elec. & Mfg. Co., Sharon, Pa.
KING, J. J., Equipment Engineer, The Pacific Tel. & Tel. Co., Park & Burnside Sts., Portland, Ore.

KIRCHHOF, WALTER H., Meter Man, Philadelphia Rapid Transit Co., 812 Sansom St., Philadelphia, Pa.
KLINGENBERG, FINN, Electrical Designer, Thomas E. Murray, Inc., 55 Duane St., New York, N. Y.
KNAUS, FRED, Contract Div., Lighting Dept., City of Seattle, 204 County City Bldg., Seattle, Wash.
KNOWLES, HUGH S., Technical Service Bureau Popular Radio Inc., 627 W. 43rd St., New York, N. Y.
KRAUSKOP, VICTOR O., Electrical Draughtsman, American Electric Power Co., 15th & Chestnut Sts., Philadelphia; res., Narberth, Pa.
KURIYAN, JOHN, Jr., Student Engineer, General Electric Co., Schenectady, N. Y.
LAUBE, LEROY FRANCIS, Testing Dept., General Electric Co., Schenectady, N. Y.
LAVIGNE, FRANCIS ANTHONY, Interior Lighting Engineer, Westinghouse Elec. & Mfg. Co., 707, 1st National Bank Bldg., San Francisco, Calif.
*LAVO, KENNETH EDWIN, Testing Dept., General Electric Co., Schenectady, N. Y.
LIEBERT, SIDNEY FREDERICK ERNEST, Engineer, Postmaster-General's Dept., Chief Electrical Engineer's Branch, Commonwealth Bldgs., Treasury Gardens, Melbourne, Australia.
LINDSTROM, CARL T., Design Engineer, Motor Engg. Dept., Westinghouse Elec. & Mfg. Co., East Pittsburgh; res., Wilkinsburg, Pa.
LINTON, STIG, Asst. Engineer, Stone & Webster, Inc., 147 Milk St., Boston, Mass.
MABEE, GEORGE CHESTER, Appraisal Engineer, Murrie & Co., 130 E. 15th St., New York, N. Y.; res., Arlington, N. J.
MACKAY, ALEXANDER, Sales Engineer, Transformer Dept.; Ferranti, Ltd., Hollinwood, Lancashire; res., Oldham, Eng.
*MANAHAN, WILLIAM T., Student Electrical Engineer, Consolidated Gas, Electric Light & Power Co. of Baltimore, Madison & Constitution Sts., Baltimore, Md.
MARSTEN, JESSE, Radio Engineer, Freed-Eisemann Radio Corp., 42 Flatbush Ave. Extension, Brooklyn, N. Y.
MARTHAKIS, GEORGE SAMUEL, Testing Dept., General Electric Co., Schenectady, N. Y.
MARTYN, CHARLES A., System Operator, Puget Sound Power & Light Co., 1306 A St., Tacoma, Wash.
MASON, HIRAM RUSSELL, Student, Ohio State University, 16-1444 N. 4th St., Columbus, Ohio.
MATELL, MOGENS TORKEL HJALMER, A. B. Bergslagens Gemensamma, Kraftforvaltning, Vasteras, Sweden.
MATHEWS, PHILIP W., Load Dispatcher, Duquesne Light Co., 435 Sixth Ave., Pittsburgh, Pa.
MATTHEWS, RALPH FAISON, 9 Warren St., Newark, N. J.
MATHEWSON, DOUGLAS E., Draftsman, Lockwood Greene & Co. Inc., 100 E. 42nd St., New York, N. Y.
McBRIDE, BRYON VICTOR, Engineer, Materials & Process Engg. Dept., Westinghouse Elec. & Mfg. Co., East Pittsburgh; res., Irwin, Pa.
McCAULEY, WILBERT MURDOCK, Dist. Manager, Railway & Industrial Engineering Co., 1207 Std. Life Bldg., Pittsburgh, Pa.
McCREIGHT, ROBERT, Jr., Asst. Technical Director, Leeds & Northrup Co., 4901 Stenton Ave., Philadelphia, Pa.
McCUAIG, DONALD ALEXANDER, Junior Electrical Engineer, Stone & Webster, Inc., 147 Milk St., Boston, Mass.
McGUIRE, P. T., Load Dispatcher, Duquesne Light Co., 435 Sixth Ave., Pittsburgh, Pa.
McINTOSH, RAYMOND SHELDON, Supt. of Electrical Construction, Cleveland Railway Co., Hanna Bldg., Cleveland, Ohio.
McKINLEY, J. G., Jr., Asst. Radio Engineer, Radio Laboratory, West Penn Power Co., Connellsville, Pa.
McNAIRY, JACOB WYATT, Railway Equipment Engg. Dept., General Electric Co., Schenectady, N. Y.
McNICHALL, JOHN FRANCIS, Chief Electrician, Gould Storage Battery Co., Depew, N. Y.
MEANS, LESTER H., Asst. General Foreman, Testing Dept., General Electric Co., Schenectady, N. Y.
MEISTER, MICHAEL H., Apprentice Engineer, Western Union Telegraph Co., Commercial Bldg., St. Louis, Mo.
MERRY, FRANK STUART, Asst. Engineer, Distribution Dept., Toronto Hydro-Electric System, 225 Yonge St., Toronto, Ont., Can.
METZ, WILLIAM R., Sales Engineer, Westinghouse Elec. & Mfg. Co., 1400 Chamber of Commerce Bldg., Pittsburgh, Pa.
MILKE, GUILLERMO NORMAN, Chief Engineer, Compania de Electricidad de Merida, S. A., Merida, Yucatan, Mex.
MITCHELL, JAMES MANN, Student Engineer, General Electric Co., 302 Lenox Road, Schenectady, N. Y.
*MOLTER, DANIEL W. C., Asst. Engineer, Relay Dept., West Power Co., 14 Wood St., Pittsburgh; res., Avalon, Pa.
MONROE, JOHN JOSEPH, Salesman, Westinghouse Elec. & Mfg. Co., 30th & Walnut Sts., Philadelphia, Pa.
MONROE, ROBERT WARNER, General Engineer, Westinghouse Elec. & Mfg. Co., East Pittsburgh; for mail, Wilkinsburg, Pa.
*MOORE, SIDNEY A., Electrical Engineer, Holeproof Hosiery Co., 404 Fowler St., Milwaukee, Wis.
MORPHEY, LLOYD ALAN, Asst. Supt. of Portland Stations, Northwestern Electric Co., Pittock Block, Portland, Ore.
MORSE, ALAN W., Draftsman, The Pacific Tel. & Tel. Co., 140 New Montgomery St., San Francisco, res., Santa Clara, Calif.
MOYERS, CHARLES GUTHRIE, Asst. to Manager, Meter Dept., West Penn Power Co., 14 Wood St., Pittsburgh, Pa.
*MOYLE, EDWARD, Student Engineer, Test Dept., General Electric Co., Schenectady, N. Y.
MUELLER, WALTER H., Toll Line Engineer, Pacific Tel. & Tel. Co., 800 Fairview Ave., Seattle, Wash.
MUIR, WILLIAM L., Meter Foreman, Puget Sound Power & Light Co., 601 Capitol Way, Olympia, Wash.
MUNTON, JOHN DACRE, Wire Chief, Atlantic Refining Co., 260 S. Broad St., Philadelphia, Pa.
MURDOCK, HARRY W., Student Engineer, Testing Dept., General Electric Co., Schenectady, N. Y.
MUZSNAY, VICTOR G., Electrical Diagram Man, Sanderson & Porter, Springdale; res., Wilkinsburg, Pa.
*NEIGHBORS, GEORGE JEFFERSON, General Electric Co., Schenectady, N. Y.
NELTHORPE, FRANK ALBERT, Jr., Asst. Dist. Engineer, Puget Sound Power & Light Co., 601 Electric Bldg., Seattle, Wash.
NEWTON, LeROY F., Salesman, Fairbanks-Morse Co., 321 E. Taylor, Portland, Ore.
OFFUTT, HENRY Y., Asst. Vice-President, First National Bank; Kentucky Title Co., Louisville, Ky.
OPSAHL, ALERT MATHIAS, Laboratory Assistant, Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa.
ORGELL, CHARLES G., Draftsman, United Gas Improvement Contracting Co., Guaranty Bldg., Broad & Cherry Sts., Philadelphia, Pa.
OSTHOFF, LINSLEY HENRY, Dist. Plant Engineer, The Pacific Tel. & Tel. Co., 800 Fairview Ave. N., Seattle, Wash.
PARADIS, ANTHONY, Engineer, The Pacific Tel. & Tel. Co., 800 Fairview Ave., Seattle, Wash.
PATON, JAMES, Jr., Sales Representative, American Electrical Works, Phillipsdale, R. I.; res., St. Louis, Mo.
PAULUS, CLARENCE FRANCIS, Elec. Engg. Dept., Cleveland Electric Illuminating Co., Cleveland, Ohio.
PEARSON, HAROLD ELMER, Student, Pratt Institute, Brooklyn, N. Y.
PECK, FRANK M., Detail Load Dispatcher, Northern Ohio Power & Light Co., Akron, Ohio.
PECK, JOHN L., General Electric Co., Erie; res., Wesleyville, Pa.
PEDLEY, HOWARD L., Junior Electrical Engineer, Commonwealth Edison Co., 72 W. Adams St., Chicago, Ill.
PERKS, JOHN A., Philadelphia Electric Co., 2301 Market St., Philadelphia; res., Newton Square, Del. Co., Pa.
*PERRY, RICHARD T., A. C. Engg. Dept., General Electric Co., Schenectady, N. Y.
PHIPPS, PAUL, Inspector, Distribution Dept., Toronto Hydro-Electric System, Toronto, Ont., Can.
PISTORIUS, LEO HENRY, Commercial Electrical Engineer, British Thomson-Houston Co., Ltd., Rugby, Eng.
PITT, FRANK ERNEST, Dist. Engineer, South Wales Electrical Power Distribution Co., Ltd., The Bungalow, Power Station, Cwmbran, Monmouth Co., Eng.
*PIXTON, WILLIAM GREEG, Testing Dept., General Electric Co., Schenectady, N. Y.
PLA, RAMON A., Office Engineer, Signal Dept., Florida East Coast Railway Co., St. Augustine, Fla.
PODGAINY, CHARLES, Radio Inspector, Freed-Eisemann Radio Corp., 40 Flatbush Extension, Brooklyn, N. Y.
PONDAY, GOVIND PRASAD, Deputy Power Station Engineer, Chaba, Simla Municipality Power Station, Simla Dist., Punjab, India.
POWELL, HENRY TAYLOR, Electrical Engineer, Louisville Gas & Electric Co., Louisville, Ky.
*PUGH, GRIFFITH CYRIL, Asst. Engineer, West Penn Power Co., 14 Wood St., Pittsburgh; res., McKeesport, Pa.
QUALLINS, GEORGE ANDREW, 237 W. 70th St., New York, N. Y.
QUINN, JOHN T., Jr., Central Office Installer, New England Tel. & Tel. Co., 51 Inman St., Cambridge; res., Roxbury, Mass.
RANKIN, G. D., Manager & Treasurer, The Hartford Faience Co., Hartford, Conn.
RASMUSSEN, DAVID, Draftsman, Duquesne Light Co., Duquesne Bldg., Pittsburgh, Pa.
*RASMUSSEN, WALTER, Service Dept., Tabulating Machine Co., 640 Mission St., San Francisco, Calif.
REED, RAYMOND B., Asst. Electrical Designer, Philadelphia Electric Co., 1035 Chestnut St., Philadelphia, Pa.
RICE, HAROLD E., General Engg. Dept., New England Tel. & Tel. Co., 50 Oliver St., Boston; res., Somerville, Mass.
RICHARDS, DANIEL, Electrician, Pennsylvania Power & Light Co., Hauto; res., Lansford, Pa.
RICHARDSON, THOMAS PURDIE, Jr., Engineer, A. A., Merrick Engineering Service, Tryon, N. C.
*ROBINSON, GEORGE WILLIAM, Testing Dept., General Electric Co., Schenectady, N. Y.
ROBINSON, ROBERT BOWES, Section Engineer, Philadelphia Co., 435 6th Ave., Pittsburgh; res., East Liberty Sta., Pittsburgh, Pa.
*RORKE, CHARLES B., General Engineer, Westinghouse Elec. & Mfg. Co., East Pittsburgh; res., Pittsburgh, Pa.
ROSS, DONALD G., Testing Dept., General Electric Co., Schenectady; res., Troy, N. Y.

ROTH, ARNOLD, Sous-directeur des Ateliers de Constructions electriques de Delle. Cie. gen. d'electricite, Chemin de Cyprian, Lyon-Villeurcanne, France.
ROTH, JAMES DORSEY, Valuation Engineer, Duquesne Light Co., 435 Sixth Ave., Pittsburgh, Pa.
ROUDEBUSH, GEORGE H., Telephone Engineer, Ohio Bell Telephone Co., 4300 Euclid Ave., Cleveland, Ohio.
RUDD, THEODORE OLIVER, Salesman, Kerite Insulated Wire & Cable Co., 30 Church St., New York, N. Y.
RUPERT, C. L., System Operator, Duquesne Light Co., 435 Sixth Ave., Pittsburgh, Pa.
RUSSELL, FREDERICK WILLIAM, Electrician, Construction Dept., Louisville Gas & Electric Co., Louisville, Ky.
SAMSON, ROY, Supt., Line Dept., Puget Sound Power & Light Co., Pike Block, Bellingham, Wash.
SASAKI, TOSHIO, Student, Mass. Institute of Technology, 281 Harvard St., Cambridge, Mass.
*SATTENSTEIN, SIDNEY LINCOLN, Asst. Electrical Engineer, B. & F. Dept., Bethlehem Steel Co., Bethlehem, Pa.
SCHREIBER, ERNST H., Engineer, The Pacific Tel. & Tel. Co., Dexter Horton Bldg., Seattle, Wash.
SCHROEDER, JOHN PAUL, Electrical Draftsman, Pacific Gas & Electric Co., 245 Market St., San Francisco, Calif.
SCHULTZ, CLARENCE FREDERICK, Load Dispatcher, Cleveland Railway Co., 733 Hanna Bldg., Cleveland, Ohio.
SHALLENBERGER, DANA KELL, System Operator, Beechbottom Power Co., Power, West Va.
SHAW, JAMES LINCOLN, Foreman, Electrical Repair Shop, Bethlehem Steel Co., Lackawanna; for mail, Buffalo, N. Y.
SILLERS, THOMAS GEORGE ARCHIBALD, Student Apprentice, Allis-Chalmers Mfg. Co., Milwaukee, Wis.
SINDERSON, L. O., Asst. Foreman, Testing Dept., General Electric Co., Schenectady, N. Y.
SLATER, WILLIAM FAVRE, Consulting Engineer, Osburn Monnett, 548 Elmwood Ave., Evanston, Ill.; res., Memphis, Tenn.
SMITH, JAMES RODERICK, Electrical Construction Engineer, Louisville Gas & Electric Co., 119 N. 3rd St., Louisville, Ky.
SMITH, PHILIP CARVER, Engineer, Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa.
SMITH, TRUEMAN TRYTHALL, Relay Tester, Puget Sound Power & Light Co., Electric Bldg., Seattle, Wash.
SNOW, EARL CARL, Asst. Foreman, Switchboard & Control Dept., Louisville Gas & Electric Co., Louisville, Ky.
SNYDER, CHARLES, Student Engineer, General Electric Co., Schenectady, N. Y.
SNYDER, JOHN NICHOLAS, Supervisor of Installation, Duquesne Light Co., Duquesne Bldg., Pittsburgh; res., Crafton Heights, Pittsburgh, Pa.
*SNYDER, REGINALD J., Engineer's Assistant, Brooklyn Edison Co., Inc., 380 Pearl St., Brooklyn, N. Y.
SORKE, WILLIAM STANLEY, Student, Bliss Electrical School, Washington, D. C.; res., Detroit, Mich.
*SPAULDING, LELAND SEIWELL, Electrician-Draftsman, Merkle Bank Bldg., Hazleton, Pa.
SPEAR, HIRAM E., Chief Draftsman, Southwestern Dist., Puget Sound Power & Light Co., Tacoma, Wash.
SPRAGUE, CARLTON STANLEY, Research Assistant, Eng. Ext. Dept., Purdue University, Lafayette, Ind.
SPROULE, HAROLD C., Electrical Substation Designer, Philadelphia Electric Co., 10th & Chestnut Sts., Philadelphia, Pa.
STACY, ROBERT P., Asst. to Vice-President, Duquesne Light Co., 435 Sixth Ave., Pittsburgh, Pa.
STENKVIST, KARL EMIL, Chief Engineer, Allmanna Svenska Electric Co., Ludvika, Sweden.
STORMS, CHARLES ARBA, Testing Dept., General Electric Co., Schenectady; res. Balston Lake, N. Y.
SUMNER, MERTON ROGERS, Construction Engineer, Philadelphia Co., 435 Sixth Ave., Pittsburgh, Pa.
SZONTAGH, JOHN R., Mechanical Draftsman, Switchboard Engg. Dept., General Electric Co., 6801 Elmwoood Ave., Philadelphia, Pa.
TAVENNER, W. B., Outside Salesman, Graybar Electric Co., 301 E. 8th St., Los Angeles, Calif.
TENNANT, RAYMOND JOHN JEFFERSON, Junior Design Engineer, Duquesne Light Co., 635 Sixth Ave., Pittsburgh, Pa.
THAYER, HARRY CURTIS, Jr., Student Engineer, Testing Dept., General Electric Co., Schenectady, N. Y.
THAYER, RAYMOND C., Telephone Engineer, Great Northern Railway Co., 820 Great Northern Bldg., St. Paul, Minn.
THEDNIGA, HENRY H., Manufacturer's Agent, 314 Seneca St., Seattle, Wash.
THOMPSON, ARTHUR WEBSTER, President, Philadelphia Co., 435 6th Ave., Pittsburgh, Pa.
THOMPSON, LAMBERT ATHELSTAN, Commercial Power Engineer, Sales Dept., Puget Sound Power & Light Co., Electric Bldg., Seattle, Wash.
THOMPSON, SYDNEY, Agent, Westinghouse Elec. International Co., Johannesburg, S. Africa.
THOMSON, JOSEPH FRASER F., Student Engineer, Testing Dept., General Electric Co., Schenectady, N. Y.
TIENKEN, WILLIAM JOHN, Jr., Student, Pratt Institute, Brooklyn, N. Y.
TROXEL, FRANKLIN DALE, Electrical Engineer, Sargent & Lundy, Inc., 72 W. Adams St., Chicago, Ill.
*TSOU, TSONG YUA, Erecting Engineer, Anderson & Meyer Co., Shanghai; Kiushing Cotton Mill, Kiukiang, Kiang-si, China.
TUCKER, JAMES ROBERT, Railroad Draftsman, Southern Pacific Co., Annex "C", Old Post Office Bldg., San Francisco, Calif.
UHLRIG, HARRY WILLIAM, Testing Dept., General Electric Co., Schenectady, N. Y.
VAN HUYSEN, JOHN WILLIAM, Sales Engineer, Garland Affoller Engineering Corp., 807 Alaska Bldg., Seattle, Wash.
WALKER, ANGUS JOSEPH, Testing Dept., Wireless Specialty Apparatus Co., 76 Atherton St., Jamaica Plain; res., Dorchester, Mass.
*WALTHER, GEORGE J., Testing Dept., General Electric Co., Schenectady, N. Y.
*WALTON, IVAN R., Control Engineer, Westinghouse Elec. & Mfg. Co., East Pittsburgh; res., Wilkinsburg, Pa.
WARNER, CLARENCE WILBUR, Student Engineer, Testing Dept., General Electric Co., Schenectady, N. Y.
*WATANABE, JOHN SHIGEZO, Graduate Student, Mass. Institute of Technology, 408 Craigie Hall, Cambridge, Mass.
WECKEL, GEORGE HERMAN, Testing Dept., General Electric Co., Schenectady, N. Y.
WEIGAND, WILLIAM F., Jr., Asst. Traffic Engineer, Philadelphia Rapid Transit Co., 1520 Spruce St., Philadelphia; res., Lansdowne, Pa.
*WELLMAN, BERTRAM, Student Engineer, General Electric Co., Schenectady, N. Y.; for mail, Springfield, Mass.
WELLS, JOHN P., Sales Engineer, Century Electric Co., 1806 Pine St., St. Louis, Mo.
WEST, JOSPEH I., Manager, The Litchfield Electric Light & Power Co., North St., Litchfield, Conn.
*WHITE, EDWARD, Central Office Equipment Engineer, New England Tel. & Tel. Co., 50 Oliver St., Boston; res., Atlantic, Mass.
WHITE, EUGENE L., Radio & Telephone Inspector, Puget Sound Power & Light Co., Electric Bldg., Seattle, Wash.
WHITEMAN, WILLIAM AMBROSE, Asst. Supt., Substations Terr "C", Monongahela West Penn Public Service Co., Wellsburg, West Va.
WICKERSHAM, W. ROY, Electrical Engineer, Westinghouse Elec. & Mfg. Co., East Pittsburgh; res., Swissvale, Pa.
WILLIAMSON, WILLIAM S., Superintendent of Buildings, Prudential Insurance Company, Broad & Bank Streets, Newark, N. J.
WILLITS, ROBERT FORD, Foreman Operator, Public Service Electric & Gas Co., Broadway & Atlantic Ave., Camden, N. J.
WILTSHIRE, ARTHUR J., Draughtsman, Marvel Equipment Co., 8810 Harvard Ave., Cleveland, Ohio.
WOOD, GEOFFREY EDGAR, Production Engineer, Westinghouse Lamp Co., New York, N. Y.
WRIGHT CHARLES THOMAS, Chief Electrician, The Pennsylvania-Ohio Power & Light Co., Toronto, Ont., Can.
WRIGHT, ROBERT B., Draftsman, Puget Sound Power & Light Co., 7th & Olive Sts., Seattle, Wash.
YODER, NORMAN W., Instrument Maker, Leeds & Northrup Co., 4901 Stenton Ave., Philadelphia, Pa.
ZIERDT, CONRAD H., Engineering Dept., Union Switch & Signal Co., Swissvale, Pa.
Total 334.
*Formerly enrolled students

ASSOCIATES REELECTED JUNE 23, 1926

BANAN, HORACE FREDERICK, Paper & Rubber Mill Engineer, Westinghouse Elec. & Mfg. Co., 10 High St., Boston, Mass.
BRAITHWAITE, WILLIAM S., Electrical Engineer, Edison Electric Illuminating Co., 39 Boylston St., Boston, Mass.
BUCHANAN, ELMER CLARENCE, Engg. Dept., The Pacific Tel. & Tel. Co., 380 Burnside St., Portland, Ore.
CARTER, THOMAS BAILEY, Division Plant Engineer, Cumberland Tel. & Tel. Company, 1101 Repbulic Bldg., Louisville, Ky.
COTTRELL, WILLIAM J., Manager, Allied Industires, Inc., 53, 4th St., Portland, Ore.
DRUMMOND, ALFRED JOHN, Engg. Dept., The United Gas Improvement Contracting Co., Broad & Arch Sts., Philadelphia; res., Upper Darby, Pa.
SHERER, CLAYTON M., Asst. in Testing Dept., Pennsylvania Water & Power Co., Holtwood, Pa.
WOODHOUSE, GEORGE E., Supt., Hydro-Electro Power Commission, 451 Davenport Road, Toronto, Ont., Can.

MEMBER REELECTED JUNE 23, 1926

BODGE, HAROLD H., Power Engineer, Fall River Electric Light Co., 65 N. Main St., Fall River, Mass.

MEMBERS ELECTED JUNE 23, 1926

BIRD, CLARENCE ARTHUR, Asst. Planning Engineer, The Detroit Edison Co., 2000 2nd St., Detroit, Mich.
DIBBLEE, JOHN, Operating Engineer, Hydro-Electric Power Commission of Ontario, Niagara Falls, Ont. Can.
FORREST, FRANK, Chief Asst. Elec. Engineer, Electric Supply Dept., Birmingham Corp., 14 Dale End, Birmingham, Eng.
GARVIN, JOHN ST. CLAIR, Telephone Engineer, Bell Telephone Laboratories, Inc., 463 West St., New York, N. Y.; res., Bogota, N. J.
GRAVES, JAMES MADISON, Vice-President & General Manager, Duquesne Light Co., 435 Sixth Ave., Pittsburgh, Pa.

HICKS, LEROY VERNON, Manager, Switchboard & Control Div., Service Dept., Westinghouse Elec. & Mfg. Co., East Pittsburgh; res., Wilkinsburg, Pa.

LOTT, HARRY CHICKALL, Engineer, Balfour, Beatty & Co., Ltd., 66 Queen St., London, E. C. 4, Eng.

LOUGHRIDGE, CLYDE HIGBEE, Consulting Engineer, 1900 Euclid Ave., Cleveland, Ohio.

PHILLIPS, ELLIS LAURUMORE, President, E. L. Phillips & Co., 50 Church St., New York, N. Y.

THOMSON, STANLEY ERIE, Operating Supt., Hydro-Electric Power Commission, Niagara Falls, Ont., Can.

TRANSFERRED TO GRADE OF FELLOW JUNE 23, 1926

BEDELL, FREDERICK, Professor of Applied Electricity, Cornell University, Ithaca, N. Y.

BOYAJIAN, ARAM, Electrical Engineer, General Electric Co., Pittsfield, Mass.

DAVIDSON, WARD F., Research Engineer, Brooklyn Edison Co., Brooklyn, N. Y.

FONDILLER, WILLIAM, in charge, General Development Laboratory, Bell Telephone Laboratories, New York, N. Y.

HUBLEY, GEORGE W., Consulting and Advisory Engineer, Louisville, Ky.

MARRIOTT, ROBERT H., Consulting Engineer, New York, N. Y.

RICHARDS, WILLIAM E., Supt., Electrical Dept., Toledo Edison Co., Toledo, Ohio.

STRENG, LEWIS S., Vice-President in charge of Operation, Louisville Gas & Electric Co., Louisville, Ky.

THOMAS, GEORGE N., Contract Engineer and Supt. of Construction, Canadian General Electric Co., Ltd., Toronto, Ont.

TRANSFERRED TO GRADE OF MEMBER JUNE 23, 1926

AMES, NORMAN B., Assistant Professor of Electrical Engineering, George Washington University, Washington, D. C.

BAILEY, RAYMOND, Chief Electrical Designer, Philadelphia Electric Co., Philadelphia, Pa.

BULLARD, WILLIAM R., Assistant Engineer, Electric Bond & Share Co., New York, N. Y.

CAMPBELL, THADDEUS C., Telephone Engineer, Systems Development Dept., Bell Telephone Laboratories, New York, N. Y.

CELIS, ATILIO, Manager-Engineer, San Juan Office of International General Electric Co., Inc., San Juan, P. R.

CHADWICK, RALPH H., Section Head, Transformer Engineering Dept., General Electric Co., Fort Wayne, Ind.

CLEARY, LEO H., Electrical Engineer, Standard Engineering Co., Washington, D. C.

CRESSEY, JOHN A., Control Engineer, South Wales Power Co., Pontypridd, Glamorgan, England.

EDISON, OSKAR E., Associate Professor of Electrical Engineering, University of Nebraska, Lincoln, Neb.

FEDER, JOSEPH B., Electrical Engineer, Chas. Cory & Son, Inc., New York, N. Y.

GARRISON, DWIGHT, Supt., Telephone Dept., Atlantic Refining Co., Philadelphia, Pa.

GAYLORD, JOHN C., Electrical Engineer, Southern California Edison Co., Los Angeles, Calif.

GORDON, LESLIE B., Chief Electrical and Power Engineer, Kelly-Springfield Tire Co., Cumberland, Md.

HALPENNY, R. H., Electrical Engineer' Southern Sierras Power Co., Riverside, Calif.

HAMILTON, JAMES T., Supt. of Equipment, New York, Westchester & Boston R. R., New York & Stamford Ry. Co., Westchester Street Ry. Co., New York, N. Y.

HECHT, J. BERNARD, Outside Plant Engineer, Tri-State Tel. & Tel. Co., St. Paul, Minn.

HEILBRUN, RICHARD, Head of firm, Dr. Richard Heilbrun, Manufacturer of Electric Appliances, Berlin, Germany.

HENTZ, ROBERT A., Electrical Engineer, Philadelphia Electric Co., Philadelphia, Pa.

HESTER, EDGAR A., Transmission Planning Engineer, Duquesne Light Co., Pittsburgh, Pa.

HODTUM, JOSEPH B., Sales Engineer, Pittsburgh Transformer Co., Pittsburgh, Pa.

HOWK, CLARENCE L., Telephone Engineer, International Standards Electric Corp., New York, N. Y.

HULL, BLAKE D., Transmission & Protection Engineer, Southwestern Bell Telephone Co., St. Louis, Mo.

KARCHER, E. KENNETH, Chief Electrical Engineer, Utica Gas & Electric Co., Utica, N. Y.

KENNEDY, S. M., Vice-President, Southern California Edison Co., Los Angeles, Calif.

KEPHART, CALVIN I., Senior Examiner, (Valuation), Interstate Commerce Commission, Washington, D. C.

KNUDSEN, H. A., Electrical & Mechanical Engineer, East Bay Municipal Utility District, Oakland, Calif.

KOCH, M. McK., Supt. Electric Distribution, Public Service Co. of Colorado, Denver, Colo.

LOUIS, H. C., Chief of Research & Test, Consolidated Gas Electric Light & Power Co., Baltimore, Md.

MACNAUGHTON, A. K., Supt. of Distribution, Blackstone Valley Gas & Electric Co., Pawtucket, R. I.

McCLELLAN, LESLIE N., Electrical Engineer, U. S. Bureau of Reclamation, Denver, Colo.

McILVAINE, H. A., Engineer, Cleveland Vacuum Tube Works, Cleveland, O.

McROBBIE, HENRY W., Supt. Substations, West Penn Power Co., Connellsville, Pa.

NELSON, EDWARD L., Engineer, Bell Telephone Laboratories, New York, N. Y.

SIMONS, DONALD M., Development Engineer, Standard Underground Cable Co., Pittsburgh, Pa.

SIMS, WILLIAM F., Field Engineer, Generating Stations, Commonwealth Edison Co., Chicago, Ill.

STEBBINS, ALDEN H., Electrical Engineer, Edward Ford Plate Glass Co., Rossford, Ohio.

STINER, H. WRAY, Commercial Engineer, General Electric Co., Cleveland, O.

VAN BOKKELEN, WILLIAM R., Chief Engineer, Coast Counties Gas & Electric Co., San Francisco, Calif.

APPLICATIONS FOR ELECTION

Applications have been received by the Secretary from the following candidates for election to membership in the Institute. Unless otherwise indicated, the applicant has applied for admission as an Associate. If the applicant has applied for direct admission to a higher grade than Associate, the grade follows immediately after the name. Any member objecting to the election of any of these candidates should so inform the Secretary before July 31, 1926.

Allen, R. L., Archbold-Brady Co., Syracuse, N. Y.

Anderson, C., Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa.

Baeckler, W., National Carbon Co., Lakewood, Ohio

Banks, H. O., Hartford Steam Boiler Inspection & Ins. Co., New York, N. Y.

Bennett, R. S., General Electric Co., Cincinnati, Ohio

Bramblett, P. F., Northwestern Light & Power Co., Sibley, Iowa

Butterworth, R. I., Bristol Gas & Electric Co., Bristol, Tenn.

Carrasco-Zanini, J., Mexican Light & Power Co., Ltd., Mexico, D. F.

Cecchetti, F., General Electric Co., Schenectady, N. Y.

Chang, Z. Z., Westinghouse Elec. & Mfg. Co., Sharon, Pa.

Curtis, H. C., Cutler-Hammer Mfg. Co., Milwaukee, Wis.

de Mulinen, E. F. H., American Brown Boveri Electric Corp., Camden, N. J.

Donovan, W., General Electric Co., Ltd., Philadelphia, Pa.

Dunkelberg, P. R., Illinois Central Railroad Co., Chicago, Ill.

Dunlap, B., Ozork Pipe Line, Ponca City, Okla.

Fogg, L. E., American Electrical Works, Phillipsdale, R. I.

Gattiker, C. H., The New York Edison Co., NewYork, N. Y.

Gilbert, C. F., Canadian Crocker-Wheeler Co., Ltd., St. Catharines, Ont., Can.

Gilroy, J. R., Commonwealth Edison Co., Chicago, Ill.

Gray, W. S., Stone & Webster, Inc., Boston, Mass.

Gronvold, I. J., Neil Electric Co., Isleton, Calif.

Haentjens, O., Barrett, Haentjens & Co., Hazleton, Pa.

Hall, I. E., (Member), Roller-Smith Co., Bethlehem, Pa.

Hammond, R. J., The Pacific Tel. & Tel. Co., Los Angeles, Calif.

Hastings, D. F., Rossiter, Tuler & McDonnell, New York, N. Y.

Heintz, W. T., Automatic Electric Co., 427 Bourse Bldg., Philadelphia, Pa.

Herne, W. W., Great Western Power Co., San Francisco, Calif.

Hildebrandt, J. L., Consolidated Elec. Lt. & Pr. Co., Baltimore, Md.

Hudd, A. E., Automatic Electric Inc., Chicago, Ill.

Humphries, P. H., Harvard University, Cambridge, Mass.

Ischinger, A. E., with Joshua R. H. Potts, Philadelphia, Pa.

Jones, R. E., (Member), Hydro-Elec. Power Commission of Ontario, Toronto, Ont., Can.

Kohlhepp, W. S., Cumberland Tel. & Tel. Co., Louisville, Ky.

Larkin, J. J., Brooklyn-Manhattan Corp., Brooklyn, N. Y.

Lessing, O., Counties Gas & Electric Co., Norristown, Pa.

Long, M., Bell Telephone Co. of Pa., Philadelphia, Pa.

MacCormick, C. M. C., General Electric Co., Schenectady, N. Y.

Mahnke, K., Pennsylvania Power & Light Co., Williamsport, Pa.

Mahoney, J. F., Brooklyn Edison Co., Brooklyn, N. Y.

Marquardt, M., Electrician, Passaic, N. J.

Nakamura, H., Toho Electric Power Co., Tokio, Japan; (For mail, Wilkinsburg, Pa.)

Nivin, D. G., (Member), Chief Elec. Inspector, City of Miami, Miami, Fla.

Palm, I. R., Sargent & Lundy, Chicago, Ill.

Patrick, R. A., Truckee River Power Co., Reno, Nev.

Pinckert, W. F., Draftsman, 1264 Bush St., San Francisco, Calif.

Rehwaldt, A. W., Sargent & Lundy, Chicago, Ill. (Applicant for re-election.)

Robinson, C. C., (Member), Member of Firm, C. M. Robinson, Richmond, Va.

Rogers, F. H., Consolidated Gas & Electric Co., Baltimore, Md.

Rudorff, D. W., Mexican Light & Power Co., Ltd., Necaxa, Puebla, Mex.

Scharf, P. B., Goodyear Industrial University, Akron, Ohio

Schuman, J. J., (Member), The Edison Elec. Ill. Co. of Boston, Boston, Mass.

Skelton, W. J., Wisconsin Telephone Co., Milwaukee, Wis.

Souza, V., Contratista de Instalaciones, Mexico City, Mex.

Staggs, N. K., The Telephone Engineering & Equipment Co., Seattle, Wash.

Stotler, E. J., Sears, Roebuck & Co., Newark, N.J. (Applicant for re-election.)

Swanson, E. R., Wisconsin Power & Light Co., Fond du Lac, Wis.
Tandberg, L. G., Wagner Electric Corp., Los Angeles, Calif.
Tillquist, D., New York Telephone Co., New York, N. Y.
Terhune, W. I., Public Service Production Co., Newark, N. J.
Tulloss, J. C., (Member), 50 Vanderbilt Ave., New York, N. Y.
Watts, W. E. G., (Member), Luscar Collieries, Luscar via Edmonton, Alta, Can.
Way, R. S., Worcester Suburban Electric Co., Uxbridge, Mass.
Weaver, R. A., Cincinnati & Suburban Bell Tel. Cincinnati, Ohio
Whisenand, O. B., Citizens Gas Co., Indianapolis, Ind.
White, W. C., (Member), Cumberland Tel. & Tel. Co., Louisville, Ky.
Zorn, F. W., (Member), American Laundry Machinery Co., New York, N. Y.
Total 66.

Foreign

Anthony, P. A. W., with A. E. Harding Frew, Brisbane, Queensland, Aust.
Baxendale, F., British-Thomson Co., Ltd., Rugby, Eng.
Bucktin, F. C., Springs-Ellesmere Power Board, Templeton, Christchurch, N. Z.
Crane, S. F., Southland Electric Power Board, Invercargill, N. Z.
Dobbs, L. J., Southland Electric Power Board, Invercargill, N. Z.
Evans, H. C. H., Newcastle City Council, Newcastle, N. S. Wales, Aust.
Keenan, H. B., Waiarapa Electric Power Board, Carterton, N. Z.
Maneckji, J. B., (Member), Industrial Engr. & Advisor, Bombay, India
Master, J. J., Tata Hydro & Andhra Valley Elec. Pr. Supply Co., Bombay, India
Masu, S., Toho Electric Power Co., Tokio, Japan
Pergler, F., Chief Engineer, City of Prague, Prague, Czechoslovakia
Pradhan, G. K., Baroda State's Power House, Baroda, India
Tzichevsky, J. A., Elec. Station Constr., U. S. S. R. Gov't., Moscow, U. S. S. R. Russia
Wight, W. C., Municipal Electricity Dept., Idgah, Simla, India
Total 14

STUDENTS ENROLLED

Balkow, Cecil, Univ. of Idaho
Billman, Albert G., South Dakota State College
Birkett, Charles M., School of Engg. of Milwaukee
Brienza, Anthony, Columbia Univ.
Brown, Cecil L., Univ. of Idaho
Boynton, Robert D., Stanford Univ.
Caruthers, Lawrence H., Yale Univ.
Caven, Waldo E., Carnegie Tech.
Chable, William J., Virginia Military Inst.
Clendenin, Arthur M., Univ. of Nebraska
Cosentine, Louis G., Univ. of Wisconsin
Curtis Lorin, Univ. of Idaho
Delaplane, R. Reyburn, Purdue Univ.
De Roo, Howard Drummond, Mass. Inst. of Tech.
Dodd, Samuel A., Cornell Univ.
Elliott, Robert G., Univ. of Idaho
Ernsberger, Edward L., Univ. of Idaho
Evans, Edmund A., Rensselaer Poly. Inst.
Fisher, John H., Northeastern Univ.
Francis, M. Clifford, Univ. of Missouri
Haber, Frank L., Univ. of Wisconsin
Hall, Clarence F., Rensselaer Polytechnic Institute
Harman, Leonard F., Univ. of Idaho
Hayward, Doyle E., Univ. of Idaho
Hertsche, Jr., J. C., Stanford Univ.
Hockings, Clarence E., Univ. of Wisconsin
Holbrook, Joseph T., Univ. of Idaho
Immer, William L., Univ. of Kansas
Justus, Chester L., Univ. of Idaho
Kellogg, Cyrene W., School of Engg. of Milwaukee
Kirk, Royal B., Purdue Univ.
Krueger, Adolph, School of Engg. of Milwaukee
Kuntz, William R., Penn. State College
Lamphere, Phineas H., Univ. of Idaho
Lanier, John S., Harvard Univ.
Lebowitz, Samuel, Univ. of Maryland
Lovewell, Kermit M., Univ. of Wisconsin
MacDonald, Charles, Pennsylvania State College
Malpass, Donald, Penn. State College
McKim, James B., Stanford Univ.
Menconi, Leonard, Cornell University
Morris, Edson L., Univ. of Idaho
Mushlitz, Arba R., Univ. of Idaho
Nerenberg, Albert C., Univ. of Michigan
Noecker, Cecil C., Michigan State College
Olmsted, Joseph N., Univ. of Colorado
Olson, Melvin C., Univ. of Wisconsin
Orsborn, Forrest M., Univ. of Colorado
Patchen, Roy R., Univ. of Idaho
Phelps, John C., Michigan State College
Poch, Waldemar J., Univ. of Michigan
Porter, Ralph E., Univ. of Missouri
Ream, John Rodney, Univ. of Utah
Reid, Edward M., Oklahoma A. & M. College
Rutherford, Francis H., Mass. Inst. of Tech.
Samida, David A., School of Engg. of Milwaukee
Schuttler, Norman N., Univ. of Idaho
Snyder, Ralph J., School of Engg. of Milwaukee
Solodoff, Vasily J., Oregon Agri. College
Stanton, Wyllys G., Yale Univ.
Stringham, Reed M., Univ. of Utah
Taylor, Richard H., Univ. of Idaho
Thomason, Jesse L., Univ. of Idaho
Van Denburg, Cornelius G., School of Engg. of Milwaukee
Verderame, John, Northeastern Univ.
White, Martin H., Univ. of Maryland
Wood, Ernest P., Worcester Poly. Tech.
Total 67

OFFICERS OF A. I. E. E. 1925-1926

President

M. I. PUPIN

Junior Past Presidents

FARLEY OSGOOD
HARRIS J. RYAN

Vice-Presidents

HAROLD B. SMITH
EDWARD BENNETT
JOHN HARISBERGER
L. F. MOREHOUSE
H. W. EALES
P. M. DOWNING
HERBERT S. SANDS
W. E. MITCHELL
ARTHUR G. PIERCE
W. P. DOBSON

Managers

H. M. HOBART
ERNEST LUNN
G. L. KNIGHT
WILLIAM M. McCONAHEY
W. K. VANDERPOEL
H. P. CHARLESWORTH
JOHN B. WHITEHEAD
J. M. BRYANT
E. B. MERRIAM
M. M. FOWLER
H. A. KIDDER
E. C. STONE

National Treasurer

GEORGE A. HAMILTON

National Secretary

F. L. HUTCHINSON

Honorary Secretary

RALPH W. POPE

LOCAL HONORARY SECRETARIES

T. J. Fleming, Calle B. Mitre 519, Buenos Aires, Argentina, S. A.
Carroll M. Mauseau, Caixa Postal No. 571, Rio de Janiero, Brazil, S. A.
Charles le Maistre, 28 Victoria St., London, S. W. 1, England.
A. S. Garfield, 45 Bd. Beausejour, Paris 16 E, France.
F. W. Willis, Tata Power Companies, Bombay House, Bombay, India.
Guido Semenza, 39 Via Monte Napoleone, Milan, Italy.
P. H. Powell, Canterbury College, Christchurch, New Zealand.
Axel F. Enstrom, 24a Grefturegatan, Stockholm, Sweden.
W. Elsdon-Dew, P. O. Box 4563, Johannesburg, Transvaal, Africa.

A. I. E. E. COMMITTEES

(A list of the personnel of Institute committees may be found in the June issue of the JOURNAL.)

GENERAL STANDING COMMITTEES AND CHAIRMEN

EXECUTIVE, M. I. Pupin
FINANCE, G. L. Knight
MEETINGS AND PAPERS, E. B. Meyer
PUBLICATION, L. F. Morehouse
COORDINATION OF INSTITUTE ACTIVITIES, Farley Osgood
BOARD OF EXAMINERS, Erich Hausmann
SECTIONS, Harold B. Smith
STUDENT BRANCHES, C. E. Magnusson
MEMBERSHIP, J. L. Woodress
HEADQUARTERS, H. A. Kidder
LAW, W. I. Slichter
PUBLIC POLICY, Gano Dunn
STANDARDS, H. S. Osborne
EDISON MEDAL, Gano Dunn
CODE OF PRINCIPLES OF PROFESSIONAL CONDUCT, John W. Lieb
COLUMBIA UNIVERSITY SCHOLARSHIP, W. I. Slichter
AWARD OF INSTITUTE PRIZES, E. B. Meyer
SAFETY CODES, Paul Spencer

SPECIAL COMMITTEES

LICENSING OF ENGINEERS, Francis Blossom
TECHNICAL ACTIVITIES, A. G. Pierce

TECHNICAL COMMITTEES AND CHAIRMEN

COMMUNICATION, H. P. Charlesworth
EDUCATION, Harold Pender
ELECTRICAL MACHINERY, H. M. Hobart
ELECTROCHEMISTRY AND ELECTROMETALLURGY, George W. Vinal
ELECTROPHYSICS, J. H. Morecroft
INSTRUMENTS AND MEASUREMENTS, A. E. Knowlton
APPLICATIONS TO IRON AND STEEL PRODUCTION, F. B. Crosby
PRODUCTION AND APPLICATION OF LIGHT, Preston S. Millar
APPLICATIONS TO MARINE WORK, L. C. Brooks
APPLICATIONS TO MINING WORK, F. L. Stone
GENERAL POWER APPLICATIONS, A. M. MacCutcheon
POWER GENERATION, Vern E. Alden
POWER TRANSMISSION AND DISTRIBUTION, Percy H. Thomas
PROTECTIVE DEVICES, E. C. Stone
RESEARCH, John B. Whitehead
TRANSPORTATION, Cary T. Hutchinson

A. I. E. E. REPRESENTATION

(The Institute is represented on the following bodies; the names of the representatives may be found in the June issue of the JOURNAL.)

AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE, COUNCIL
AMERICAN BUREAU OF WELDING
AMERICAN COMMITTEE ON ELECTROLYSIS
AMERICAN ENGINEERING COUNCIL
AMERICAN ENGINEERING STANDARDS COMMITTEE
AMERICAN MARINE STANDARDS COMMITTEE
AMERICAN YEAR BOOK, ADVISORY BOARD
APPARATUS MAKERS AND USERS COMMITTEE
BOARD OF TRUSTEES, UNITED ENGINEERING SOCIETY
CHARLES A. COFFIN FELLOWSHIP AND RESEARCH FUND COMMITTEE
COMMITTEE ON ELIMINATION OF FATIGUE, SOCIETY OF INDUSTRIAL ENGINEERS
ENGINEERING FOUNDATION BOARD
JOHN FRITZ MEDAL BOARD OF AWARD
JOINT COMMITTEE ON WELDED RAIL JOINTS
JOINT CONFERENCE COMMITTEE OF FOUR FOUNDER SOCIETIES
LIBRARY BOARD, UNITED ENGINEERING SOCIETY
NATIONAL FIRE PROTECTION ASSOCIATION, ELECTRICAL COMMITTEE
NATIONAL FIRE WASTE COUNCIL
NATIONAL MUSEUM OF ENGINEERING AND INDUSTRY, BOARD OF TRUSTEES
NATIONAL RESEARCH COUNCIL, ENGINEERING DIVISION
NATIONAL SAFETY COUNCIL, ELECTRICAL COMMITTEE OF ENGINEERING SECTION
THE NEWCOMEN SOCIETY
RADIO ADVISORY COMMITTEE, BUREAU OF STANDARDS
SOCIETY FOR THE PROMOTION OF ENGINEERING EDUCATION, BOARD OF INVESTIGATION AND COORDINATION
U. S. NATIONAL COMMITTEE OF THE INTERNATIONAL ELECTROTECHNICAL COMMISSION
U. S. NATIONAL COMMITTEE OF THE INTERNATIONAL ILLUMINATION COMMISSION
WASHINGTON AWARD, COMMISSION OF

LIST OF SECTIONS

Name	Chairman	Secretary
Akron	Ralph Higgins	John Grotzinger, 64 Marguerite Ave., Cuyahoga Falls, Ohio
Atlanta	W. E. Gathright	W. F. Oliver, Box 2211, Atlanta, Ga.
Baltimore	W. B. Kouwenhoven	R. T. Greer, Madison St. Building, Baltimore, Md.
Boston	J. W. Kidder	W. H. Colburn, 39 Boylston Street, Boston, Mass.
Chicago	Carl Lee	B. E. Ward, Room 1679, 230 S. Clark St., Chicago, Ill.
Cincinnati	H. C. Blackwell	E. S. Fields, Union Gas & Electric Co., Cincinnati, Ohio
Cleveland	Chester L. Dows	J. F. Schnable, 3503 Mapledale Ave., Cleveland, Ohio
Columbus	R. J. B. Feather	W. T. Schumaker, 25½ North High St., Columbus, Ohio
Connecticut	A. A. Packard	A. E. Knowlton, Dunham Laboratory, Yale University, New Haven, Conn.
Denver	V. L. Board	R. B. Bonney, Telephone Building, P. O. Box 960, Denver, Colo.
Detroit-Ann Arbor	G. B. McCabe	Harold Cole, Detroit Edison Co., 2000 Second Ave., Detroit, Mich.
Erie	H. J. Hansen	L H. Curtis, General Electric Co., Erie, Pa.
Fort Wayne	E. L. Gaines	D. W. Merchant, General Electric Co., Fort Wayne, Ind.
Indianapolis-Lafayette	H. M. Anthony	J. B. Bailey, 48 Monument Circle, Indianapolis, Ind.
Ithaca	J. G. Pertsch, Jr.	Geo. F. Bason, Cornell University, Ithaca, N. Y.
Kansas City	R. L. Baldwin	S. M. DeCamp, 510 Dwight Bldg., Kansas City, Mo.
Lehigh Valley	W. H. Lesser	G. W. Brooks, Pennsylvania Power & Light Co., Allentown, Pa.
Los Angeles	R. A. Hopkins	R. E. Cunningham, 1725 Camden Ave., So. Pasadena, Calif.
Lynn	E. D. Dickinson	F. S. Jones, General Electric Co., Lynn, Mass.

LIST OF SECTIONS—*Continued*

Name	Chairman	Secretary
Madison	L. E. A. Kelso	Leo J. Peters, University of Wisconsin, Madison, Wis.
Mexico	E. F. Lopez	H. Larralde, Isabel La Catolica, 33 Mexico, D. F., Mexico
Milwaukee	H. R. Huntley	L. F. Seybold, 446 Public Service Building, Milwaukee, Wis.
Minnesota	A. G. Dewars	J. E. Sumpter, 919-23 Security Building, Minneapolis, Minn.
Nebraska	O. J. Ferguson	C. W. Minard, 509 Electric Building, Omaha, Neb.
New York	H. A. Kidder	H. V. Bozell, Bonbright & Co., 25 Nassau St., New York, N. Y.
Niagara Frontier	J. Allen Johnson	A. W. Underhill, Jr., 606 Lafayette Building, Buffalo, N. Y.
Oklahoma	E. R. Page	C. C. Stewart, Oklahoma Gas & Elec. Co., Norman, Okla.
Panama	L. W. Parsons	I. F. McIlhenny, Box 413, Balboa Heights, C. Z.
Philadelphia	Nathan Shute	R. H. Silbert, 2301 Market St., Philadelphia, Pa.
Pittsburgh	G. S. Humphrey	W. C. Goodwin, Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa.
Pittsfield	E. D. Eby	C. H. Kline, General Electric Co., Pittsfield, Mass.
Portland, Ore.	L. W. Ross	J. C. Henkle, Hawthorne Building, Portland, Ore.
Providence	W. P. Field	F. N. Tompkins, Brown University, Providence, R. I.
Rochester	A. E. Soderholm	Earl C. Karker, Mechanics Institute, Rochester, N. Y.
St. Louis	Fred D. Lyon	Ralf T. Toensfeldt, 311 City Hall, St. Louis, Mo.
San Francisco	R. C. Powell	A. G. Jones, 807 Rialto Building, San Francisco, Calif.
Saskatchewan	E. W. Bull	W. P. Brattle, Dept. of Telephones, Parliament Bldgs., Regina, Sask.
Schenectady	W. J. Davis, Jr.	W. E. Saupe, Bldg. No. 41, General Electric Co., Schenectady, N. Y.
Seattle	E. A. Loew	C. E. Mong, 505 Telephone Building, Seattle, Wash.
Sharon	W. M. Dann	L. H. Hill, Westinghouse Elec. & Mfg. Co., Sharon, Pa.
Southern Virginia	W. S. Rodman	J. H. Berry, 1338 Rockbridge Ave., Norfolk, Va.
Spokane	G. S. Covey	Richard McKay, Washington Water Power Co., Lincoln & Trent, Spokane, Wash.
Springfield, Mass.	R. P. King	J. Frank Murray, 251 Wilbraham Ave., Springfield, Mass.
Syracuse	W. C. Pearce	L. N. Street, College of Applied Science, Syracuse University, Syracuse, N. Y.
Toledo	A. H. Stebbins	Max Neuber, 1257 Fernwood Ave., Toledo, Ohio
Toronto	L. B. Chubbuck	W. L. Amos, Hydro-Elec. Power Commission, 190 University Ave., Toronto, Ont.
Urbana	C. A. Keener	J. T. Tykociner, 300 Electrical Laboratory, University of Illinois, Urbana, Ill.
Utah	John Salberg	D. L. Brundige, Utah Pr. & Lt. Co., Box 1790, Salt Lake City, Utah.
Vancouver	A. Vilstrup	C. W. Colvin, B. C. Elec. Railway Co., 425 Carroll St., Vancouver, B. C.
Washington, D. C.	A. F. E. Horn	L. E. Reed, Potomac Elec. Pr. Co., 14th & C Sts., N. W., Washington, D. C.
Worcester	E. T. Harrop	Fred B. Crosby, 15 Belmont St., Worcester, Mass.
Total 51		

LIST OF BRANCHES

Name and Location	Chairman	Secretary	Counselor (Member of Faculty)
Alabama Polytechnic Institute, Auburn, Ala	J. D. Stewart	I. L. Knox	W. W. Hill
Alabama, University of, University, Ala	C. E. Rankin	Sewell St. John	
Arizona, University of, Tucson, Ariz	C. A. Rollins	J. W. Cruse	Paul Cloke

DIGEST OF CURRENT INDUSTRIAL NEWS

NEW CATALOGUES AND OTHER PUBLICATIONS

Mailed to interested readers by issuing companies

Regulators.—Bulletin 1734, 56 pp. Describes regulators for generator-voltage control. Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa.

Transformers.—Bulletin 2055, 4 pp. Describes the construction and operation of the Pittsburgh transformer tap changer. Pittsburgh Transformer Company, Columbus & Preble Avenues, Pittsburgh, Pa.

Static Condensers.—Bulletin 20286, 4 pp. Describes static condensers for power factor correction on motor circuits of 220, 440, and 550 volts. Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa.

Grounds.—Bulletin, 8 pp., "Electrical Characteristics of Driven Grounds;" bulletin, 4 pp., "Non-Rusting Ground Rods;" bulletin, 4 pp., "Non-Rusting Overhead Ground Wires." Copperweld Steel Company, Rankin, Pa.

Circuit Breaker Time Limit Attachments. Bulletin 530, supplement, 4 pp. Describes Roller-Smith direct-acting time limit attachments for standard type circuit breakers. Roller-Smith Company, 12 Park Place, New York.

Insulator Protection.—Bulletin, 32 pp., "Taking the 'T' Out of Lightning." Describes Locke grading shield and arcing horn equipment for the protection of insulators. Locke Insulator Corporation, Baltimore, Md.

Power Factor Correction.—Bulletin 146, 24 pp., "Power Factor Correction by the Consumer." Describes the experience of the American Gas & Electric Company with power factor correction. Wagner Electric Corporation, St. Louis, Mo.

NOTES OF THE INDUSTRY

The Master Electric Company, Dayton, Ohio, announces the opening of a district office at 1725 Brandywine Street, Philadelphia, where a stock of motors will be carried. The new office will be in charge of William F. Grau.

Lapp Insulator Co., Inc., LeRoy, N. Y., announces the appointment of the Van Rosen Company, 141 Milk Street, Boston, as representative for the New England territory. The Van Rosen Company also represents the Delta-Star Electric Company and the Packard Electric Company.

The Timken Roller Bearing Company, Canton, Ohio, has promoted G. W. Curtis from industrial equipment engineer to district manager of sales, industrial division, for the Milwaukee territory. Mr. Curtis will work with R. W. Ballentine, who previously handled this territory. S. M. Weckstein succeeds Mr. Curtis as industrial equipment engineer.

The Sangamo Electric Company, Springfield, Ill., announces the appointment of Reginal M. Campbell, special representative, with headquarters at 50 Church Street, New York, who will have complete management of all watthour meter business in the metropolitan district. Mr. Campbell will be assisted by W. S. Boult. T. B. Rhoades will continue in charge of radio and amperehour meter sales as well as of the service department.

The Burndy Engineering Company, New York, manufacturers of high-tension bus equipment, announces the appointment of the H. M. Thomas Company, San Francisco, as California representative. The growth of business in the field, and the necessity of quick action in the filling of orders, led to the appointment of a special representative. Preparations are being considered to warehouse the standard Burndy line of connectors for copper tubing and cable in San Francisco, thus establishing a quick shipping point for the west coast.

Banks Huge Investors in Electric Utilities.—In the first four months of this year the financial institutions of the United States, which includes insurance companies, savings banks, national and state banks and trust companies, invested more than $427,000,000 in the bonds of the electric utility industry. In the same four months more than $68,000,000 of electric utility shares were sold to the public. That total of $495,000,000 invested in the electric industry does not include many millions of dollars of securities distributed through the customer-owner plan. The total electric utility stock and bond issues from June 1, 1925 to May 1, 1926, was $979,000,000.

The Conowingo Project—Giant of Hydroelectric Developments.—Second only to that of the Niagara Falls Power Company, and surpassing Muscle Shoals, will be the enormous hydroelectric plant which is being built by Stone and Webster for the Philadelphia Electric Power Company on the Susquehanna River, within four miles of tidewater in the state of Maryland. A dam 4800 feet long—three hundred feet longer than the Muscle Shoals dam—is being built across the river to form a reservoir of 8100 acres. The impounded water will drive waterwheel-driven electric generators of large size, and the energy will be sent over high voltage transmission lines into Philadelphia, 75 miles away.

Ultimately this hydroelectric station will contain 11 generators, each rated at 50,000 horse power, or 36,000 kilowatts. The initial installation will include seven of these units, giving the station 350,000 horse power; the Niagara Falls Power Company development produces 452,500 horse power, and Muscle Shoals 260,000 horse power. Four of the huge waterwheel-driven generators for Conowingo are now being made by the General Electric Company. They are technically rated at 40,000 kilovolt-amperes, 90 per cent power factor, and 13,800 volts, with a speed of 81.8 revolutions per minute. It is expected that 1,360,000,000 kilowatt-hours of energy will be produced by the Conowingo plant in the average year; three-quarters of a million tons of coal a year will be saved thereby.

The electric current, produced by the generators at 13,800 volts, will be stepped up to 220,000 volts by transformers and at this pressure sent over two transmission lines to Philadelphia. Each line will have sufficient capacity to carry the full load in case of trouble with the other one. When the final four generators are added to the power station, a third transmission line will be constructed.

The Conowingo hydroelectric development will be coordinated with the great steam-turbine generating plants of the company so that the water power will be used to supply the base load of the system when the flow of the river is ample, and the steam stations to supply the peak load. When the river flow is low, the steam stations will be used for carrying the base load, and the water power will be called upon only for peak loads. When the river flow is sufficient for full operation, Conowingo will supply 231,000 kilowatts for base load; when the river is low, the enormous reservoir will be called upon, and statistics covering a period of 35 years show that in the driest period of the year Conowingo will be able to supply 190,000 kilowatts for peak loads.

Construction of the 8100-acre reservoir means that the little town of Conowingo, with 200 inhabitants, must be abandoned; fifteen miles of a line of the Pennsylvania Railroad must be relocated; and five miles of main highway from Baltimore to Philadelphia must be built, with a bridge over the dam to replace the one which will be submerged.

The Susquehanna watershed of 27,000 square miles includes a large part of the central section of Pennsylvania, considerable of southern New York state, and a bit of northeastern Maryland. The average river flow is 40,000 cubic feet per second.

Research in Pure Science

The National Academy of Sciences is making a strong effort to raise a national research endowment of \$20,000,000 for research in pure science. The committee under which this movement is being fostered is under the chairmanship of Herbert Hoover and contains the names of such well-known scientists and engineers as John J. Carty, Frank B. Jewett, Gano Dunn, Robert A. Millikan and Henry S. Pritchett in addition to many names of prominent financiers and executives. Such an endowment will make possible uninterrupted investigations in pure science which now are necessarily limited.

The economic and financial advantages of such research cannot be overestimated. Its purpose is to increase and strengthen American contributions to the mathematical, physical and biological sciences by the creation of a national fund for skilled investigators, who will be selected, by the best qualified authorities in the National Academy of Sciences, from among the ablest and most productive investigators engaged in pure science research. Appropriations will be made for a fixed period of years, subject to renewal if circumstances warrant it.

Such fundamental research as these investigators are engaged in is the foundation upon which modern economic and industrial progress depend. Without their efforts the welfare of mankind would materially suffer and industrial development would be at a standstill.

A. I. E. E. Convention Affords Proof of Engineering Competency

Exceedingly well worth while was the annual convention of the American Institute of Electrical Engineers, held at White Sulphur Springs, West Va., last week. The executives of the Institute stressed the importance of engineering participation in all national affairs. The technical committees made reports which showed the status of the art and outlined the developments needed. Several fine technical papers were presented which gave rise to profitable discussions. The meeting, in short, gave evidence of entire competency on the part of electrical engineers to meet their responsibilities.

The subject of standards received an unusual amount of attention, and it is interesting to note that the American Engineering Standards Committee and the embryonic International Standards Association owe their formation to the fact that electrical engineers had shown by their own organizations that standards could be made and were needed. The A. I. E. E. standards committee and the International Electrotechnical Commission can well be proud that they were the originators of standardizing agencies of still broader scope.

Surveyed as a whole, the art of electrical engineering is well in hand and yet has very great possibilities for development. The address of Dr. Pupin showed the great tasks still to be done before electrical engineers can rest content. Yet a perspective view of this convention gives rise to the conviction that under the banner of the Institute electrical engineers will conquer all difficulties.—*Electrical World.*

Some Leaders of the A. I. E. E.

E. Wilbur Rice, Jr., thirtieth president of the Institute, 1917-1918, was born at La Crosse, Wis., May 6, 1862.

Graduating with honors in his class in the Central High School of Philadelphia in 1880, he became assistant to Professor Elihu Thomson in the American Electric Company, New Britain, Conn., then newly formed to manufacture arc lighting apparatus under the Thomson-Houston patents.

Two years later the American Electric Company was re-named the Thomson-Houston Electric Company and removed to Lynn, Mass., Mr. Rice becoming Works Superintendent and Consulting Engineer. In that dual capacity, he built up the technical and manufacturing side of the enterprise.

After the organization of the General Electric Company, Mr. Rice was made chief engineer and chairman of its Manufacturing Committee, in charge of all engineering and manufacturing operations, and in 1896 was elected vice-president. A record of his engineering activities thenceforward for a quarter of a century is an integral part of industrial history in the electrical field during that period—the history of the development of long distance electrical transmission of energy, distributing systems of polyphase currents, the rotary converter, the Curtis type of steam turbine, the tungsten lamp, and of many other applications now classed as epochal.

In 1903, Mr. Rice received his degree from Harvard University; the degree of D. Sc. in 1906 from Union

College; the degree of Doctor of Engineering in 1918 from Rensselaer Polytechnic Institute; and in 1923 the degree of D. Sc. from the University of Pennsylvania.

Apart from his work as an individual, always valuable and noteworthy in itself, he possessed, to a marked degree, the high qualities of a teacher. An example of his power to mobilize a high form of human effort and give it effective use, is the research laboratory at Schenectady, with its brilliant personnel and complete and up-to-date equipment for investigation and experiment. Others helped to plan this famous institution, even to a greater extent than he, according to his own testimony, making it what it is, but it was he who supplied the rare combination of courage and vision required to carry it through the early stages of its development.

So conspicuous have been Mr. Rice's activities as an engineer that in the sketches of his career heretofore published little has been said of his service as a business executive, particularly before he was chosen president of the General Electric Company. To him is due the major credit for the development in earlier years of the unique factory system of that corporation, with its wide spread departmental units, each having definite responsibilities and ample scope for self-expression and achievement, but all so correlated as to make needed control from a central point easy as well as effective.

With an engineer's discernment, as well as a clear perception of social and moral values, he was one of America's first industrial leaders to see the importance of that contact which has lately been secured by many corporations through works council plans. The principle of employe representation was applied by him to established procedure, so far as it was then practicable, long before it was publicly enunciated.

Biographies of Mr. Rice refer to his inventive genius. That he has been prolific as an inventor, despite the multitude of administrative duties demanding his attention, is indicated in part by the fact that there have been granted him more than 100 patents.

Besides being past president of the A. I. E. E., he is a member of the Institution of Civil Engineers and the Institution of Electrical Engineers of Great Britain. a member of the Engineers and University Clubs of New York, the University Club of Boston, and The Pilgrims. After the Paris Exposition in 1900, he was created Chevalier of the Legion of Honor, and in 1917 he received from the Emperor of Japan the decoration of the Third Order of the Rising Sun.

Mr. Rice served as President of the General Electric Company for about ten years, relinquishing that office in 1922 and becoming Honorary Chairman of the Board of Directors.

The writings of Mr. Rice have not been voluminous, as the leisure required for sustained literary work has never been his. In a paper presented by him at a memorial service for Steinmetz in October, 1923, the work of that rare genius, from the time that he landed in this country, a penniless immigrant, till his death shocked the scientific world, was vividly portrayed. A comprehensive review entitled "New Fields of Research for Power Development" was prepared by him for the First World Power Congress held in London, June 30th to July 12th, 1924.

Artificial Light For Plant Growth

Slowed-up moving pictures just taken by Carl Wallen and R. S. Green, New York motion picture camera men, of a number of different plants grown under electric light by the Westinghouse Lamp Company, in co-operation with Peter Henderson & Son, seedsmen in their greenhouses in Jersey City, N. J., prove conclusively that through the use of artificial light plants can be forced or retarded to conform to a predetermined schedule. The motion pictures were taken for the purpose of registering the exact degree of acceleration in the growth of the plants when forced by artificial light, and to determine at which stage of the plant's blossoming the light has the maximum effect. The pictures show that the blooming was greatly speeded up, some flowers, such as tulips, for instance, coming from tight buds to full bloom in less than an hour.

Tests made by Westinghouse engineers some time ago proved that artificial light can be used to stimulate the growth of many varieties of plants. At that time photographic records were made of the progress of the plants, which were grown with a combination of daylight and the added assistance of artificial light for several hours nightly, but the "still" photographs having been made at intervals of several days each, they failed to give accurate data, the effect of the light varying at different growing stages. The motion pictures have been taken with a camera which was slowed up to a predetermined number of pictures per hour through the use of gears and a motor, with a rheostat to control the speed.—*The Electrical News* (Toronto).

Radiation from Carbon Arcs

Investigating the radiation from the carbon arc is a matter of great importance in the treatment of diseases by exposure to light, especially sunlight. However, sunlight can not always be obtained, hence the demand for an artificial source approaching sunlight in its characteristics.

An investigation by the Bureau of Standards is being made in duplicate: (1) By mapping the ultraviolet spectrum by means of a quartz spectroradiometer, and (2) by measuring the spectral components of the total radiation emitted by the arc, by using a thermopile and screens which completely absorb certain spectral regions and freely transmit others.

The high-intensity arc (120 amperes) has been found to be closest to the sun in spectral composition. It emits considerable radiation of wave lengths longer than 4 μ, which are not in the solar beam, but this can be eliminated easily by using a window of fused quartz, which absorbs the long infra-red rays.

Abridgment of

Behavior of Radio Receiving Systems to Signals and to Interference

BY LEO JAMES PETERS[1]

Associate, A. I. E. E.

Synopsis.—*This paper develops a point of view and method by means of which it is possible to arrive at many of the transient effects occurring in radio systems by a consideration of steady-state properties alone. The scheme is to replace the voltages in radio receiving systems due to interference and signals by a group of generators having the correct voltages and frequencies. These generators can be thought of as having been in the circuit for an indefinitely long time, so that only the steady-state response of the system need be considered. The generators which replace the voltages induced in an antenna by interrupted continuous wave stations, by spark telegraph stations, by telephone stations and by static are worked out. The desirable properties of radio receiving systems for receiving various types of signals through interference are arrived at and an ideal system is described which may be used as a standard of reference for judging the merits of any actual frequency selecting system. It is shown that this ideal system reduces the interference from all sources to the smallest possible value which can be obtained in a system which makes use of frequency selection to reduce interference. The paper thus arrives at the degree to which interference can be mitigated by frequency-selection methods. In order to illustrate the method of treating actual systems, calculations are given for a simple series receiver. The interference caused by transmitting stations of various types and by static is discussed and the factors determining such interference are pointed out.*

Part I. Character of the Signal Voltages Induced in Antennas and the Desirable Properties of Frequency Selection Systems for Receiving the Signals

1. Introduction and Purpose

THE behavior of a radio receiving system, both to signals and to interference, depends upon the properties of the system, in the transient state. It is very often a difficult problem to arrive at the transient-state properties of a system, whereas the formulation of the steady-state properties is a relatively easy matter. It is the purpose of this paper to develop a very simple but effective way of answering some of the questions which arise in dealing with the effects of both signals and interference upon radio receiving systems when the steady-state properties of the system are known, or of arriving at the best steady-state properties of a system for receiving a given signal through interference. The primary purpose of the paper is to establish a view-point from which to judge the merits and the limitations of receiving systems, and also to arrive at the interference produced by transmitting systems of various types. Since the primary purpose of the paper is to establish a point of view and a method, only a few problems illustrating the method are discussed.

The solution for the transient properties of a circuit network can be made to depend upon the steady-state solution, if the impressed voltage can be represented from $t = -\infty$ to $t = +\infty$ as a Fourier integral. This method has been used by Carson, Fry, and the author for observing the general behavior of circuits in the transient state. Carson has used this method to formulate the response to static impulses of those radio receiving systems in which the principle of frequency selection is used to reduce interference. Milner has used the Fourier series expansion to calculate the arrival current in submarine cables. These general methods, however, lead into fields of mathematics which are unfamiliar to many engineers, but they suggest a very simple and powerful but less general method of handling many problems that arise in radio communication. This paper has a twofold purpose; first, of pointing out these simple methods with the hope that it may aid in giving the method the general use its power warrants, and second, to arrive at some interesting and useful conclusions as to the effects of signals and interference upon radio receiving systems.

2. Introduction to the Method of Treatment

Fig. 1 shows an alternator delivering a pure sine wave feeding a transformer on open circuit through a long

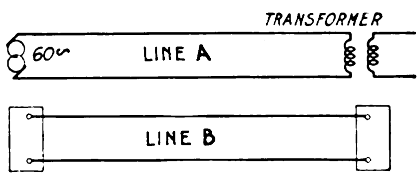

FIG. 1

line, A. Parallel to this line there is another line, B, which may be a telephone circuit. We wish to find the effect of line A upon line B. As is generally known, the current in line A has the form shown by Fig. 2. This current can be broken up into the two sine waves shown by Fig. 3. One of these sine waves has a frequency of 60 cycles per second and an amplitude I. The other has a frequency of 180 cycles per second and an amplitude of $1/4\ I$. If the mutual inductance between the lines is M, then the voltage induced in the

1. Assistant Professor of Electrical Engineering, the University of Wisconsin.

Presented at the Regional Meeting of District No. 5 of the A. I. E. E., Madison, Wis., May 6-7, 1926.

line B is composed of two parts; one part has a frequency of 60 cycles per second and an amplitude of $2\,\pi\,60\,I\,M$, while the other part has a frequency of 180 cycles per second and an amplitude of $2\,\pi\,180\,\frac{I}{4}\,M$. If the amplitude of the 60-cycle voltage is represented by E, then the amplitude of the 180-cycle voltage is $3/4\,(E)$. Then we can forget all about line A if, in line B, we introduce two alternators, one having a frequency of 60 cycles per second and a voltage of E, and the other having a frequency of 180 cycles per second and a

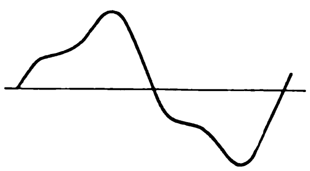

FIG. 2

voltage of $3/4\,(E)$; that is, we can calculate the effect of line A upon line B by considering only the system shown by Fig. 4.

The scheme used above for finding the effect of line A on line B is the one used throughout this paper for finding the effect of any voltage induced in an antenna upon the receiving system; for example, the voltage is replaced by a group of alternators having the correct frequencies and the correct voltages. The receiving system will then be represented schematically, as shown by Fig. 5. The generators are assumed to have no impedance and serve only as a device for fixing the

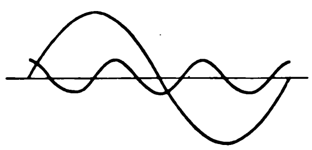

FIG. 3

attention on a sine wave of voltage having a given frequency and amplitude. Use is made of Fourier's expansion for obtaining the voltage and frequency of each alternator. Since each alternator is assumed to have been in the circuit for an indefinitely long time, only the steady-state properties of the receiving system need be considered.

3. INTERRUPTED CONTINUOUS WAVE TELEGRAPHY

The voltage induced in a receiving antenna by an interrupted continuous wave transmitter is assumed to have the form shown schematically by Fig. 6. In this figure, $2\,T$ represents the total time interval of a signal and the succeeding space, $2\,qT$ represents the signal time interval, and $2\,pT$ represents the space time interval. In order to simplify the calculations, it will be assumed that there is a complete number of cycles of the operating frequency in the time intervals qT and pT and that $p = q$. Under these conditions, if the operating frequency of the transmitting station has the value $f_0 = \frac{\omega}{2\,\pi}$, we can arrive at the following information relative to the generators which replace the

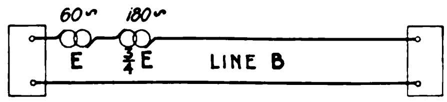

FIG. 4

voltage induced in the receiving antenna by an I. C. W. transmitter.

One generator has a frequency equal to the operating frequency, f_0. This generator has a voltage equal to $\frac{E}{2}$. Other generator frequencies in the vicinity of the operating frequency are:

$$f_n = f_0 \pm \frac{n}{2\,T},\ n = 1, 3, 5, 7 \text{ etc.} \qquad (1)$$

The voltage of the generator having the frequency f_n is:

$$E_n \text{ (peak value)} = \frac{E}{n\,\pi} \qquad (2)$$

These facts are brought out in a striking manner by

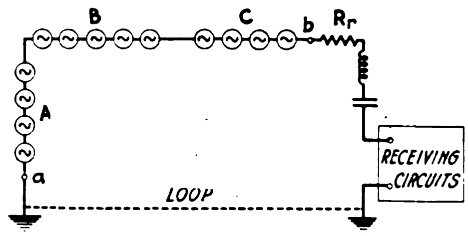

FIG. 5

the curve of Fig. 7. This curve is plotted with the ratios of the absolute value of the generator voltage to E as ordinates and with values of n as abscissa. Values of n are used as abscissa in order to make the curve hold

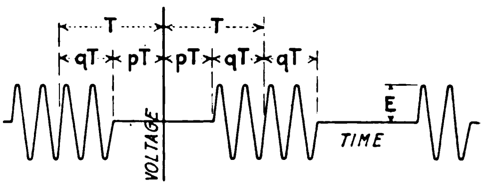

FIG. 6

for all speeds of transmission. To convert the abscissa scale to generator frequencies use is made of the relation:

$$\text{(Gen. freq.)} = f_0 + \frac{n}{2\,T} \qquad (3)$$

At 30 words per minute this relation becomes:

$$(\text{Gen. freq.}) = f_0 + 10\,n \qquad (4)$$

at 150 words per minute it becomes

$$(\text{Gen. freq.}) = f_0 + 50\,n. \qquad (5)$$

Thus, a generator having a given ratio of voltage to E is five times as far removed in frequency from the operating frequency at a transmitting speed of 150 words per minute as at a transmitting speed of 30 words per minute. This fact, as we shall see later, has an important bearing upon the design of the receiving system and also upon the amount of interference created by the transmitting station.

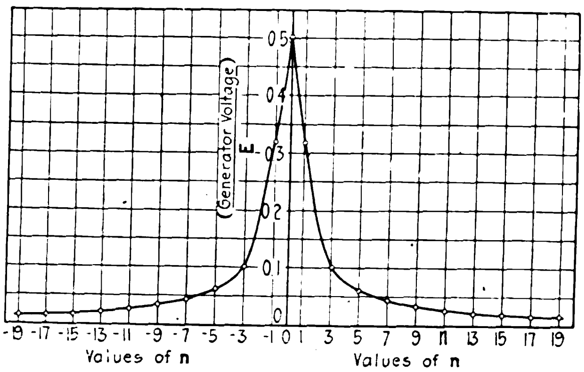

FIG. 7—INTERRUPTED C. W. TELEGRAPHY—VARIATION OF GENERATOR VOLTAGE WITH FREQUENCY—GENERATOR FREQUENCY

$= f_0 + \dfrac{n}{2T}$

$n = 0, \pm 1, \pm 3, \pm 5$, etc.
f_0 — 70 at 30 words per min.
f_0 — 350 at 150 words per min.

The desirable frequency response characteristics of the interrupted continuous wave receiving system can now be obtained. If the system passes currents having the operating frequency f_0, and eliminates currents of all other frequencies a continuous tone would be heard in the receivers and the dots and spaces could not be distinguished from each other; that is, no signals would be received. If the system passes currents of all frequencies with the same ease, the high frequency output would have the same wave form as the induced voltage, Fig. 6. This latter condition would lead to the distinguishing of the signals, but the system would have no selectivity against interference. The best circuit then would be one which passes just enough frequencies to make the signals distinguishable and eliminates all others. Let us assume that, in order to make the signals distinguishable, the receiving system must respond freely to all generators having a voltage greater than or equal to r decimal parts of the voltage of the generator the frequency of which is f_0; that is, the system must respond freely to all generators having a voltage equal to or greater than $\dfrac{r\,E}{2}$. Now the generator with a frequency of $f_0 \pm \dfrac{n}{2\,T}$ has a voltage equal to $\dfrac{E}{n\,\pi}$. We therefore write:

$$\left(\frac{E}{n\,\pi}\right)\frac{2}{E} = r$$

$$n_r \text{ is the odd number closest to } \frac{2}{r\,\pi} \qquad (6)$$

The receiving system, therefore, must pass a band of frequencies $\dfrac{n_r}{T}$ wide centered on the frequency f_0.

Let us define an ideal receiving system as one which has the following properties:

1. A radiation resistance R_r
2. No wasteful resistance
3. Acting as a pure resistance of magnitude $2\,R_r$ to frequencies lying in the range $f_0 \pm \dfrac{n_r}{2\,T}$.
4. Currents having frequencies lying in the range given by 3 shall be passed on to the detector either with a uniform amplification or without attenuation.
5. Currents of all other frequencies shall be eliminated before reaching the detector.

A system having the above properties is called an ideal system because it represents the best possible frequency selection system for receiving I. C. W. signals through interference. This ideal system can be only approximated, more or less imperfectly, in practise; but any actual receiving system, basing its selectivity upon frequency selection, should be made to fulfill the conditions stated as closely as possible.

The band of frequencies which the receiving system must pass freely is $\dfrac{n_r}{T}$. Now as both n_r and T are independent of f_0, so the band width is independent of the operating wave length. n_r is also independent of the speed of signal transmission, while T varies inversely as the speed of transmission. Therefore, the frequency band which the receiving system must transmit freely varies directly with the sending speed. Thus, the transmitted band width at 150 words per minute would be five times as great as at 30 words per minute.

It can be shown that the power available in the waves is

$$P_a = \frac{E^2}{16\,R_r} \qquad (7)$$

and that the power utilized by the ideal receiver is

$$P = \frac{E^2}{8 R_r} \left[\frac{1}{4} + \frac{2}{\pi^2} \sum \frac{1}{s^2} \right] \quad (8)$$

$s = 1, 3, 5 \ . \ . \ . \ n_r$

Calculations indicate that if $n_r = 3$, the intervals and dots will be easily distinguishable. When n_r has this value, the ratio of the power utilized by the ideal receiver to the power available is 0.9.

With the above value of n_r, the ideal system would pass freely a band of frequencies lying between $f_0 - 30$ cycles per second and $f_0 + 30$ cycles per second at 30 words per minute. At 150 words per minute the band passed would be between $f_0 - 150$ cycles per second and $f_0 + 150$ cycles per second.

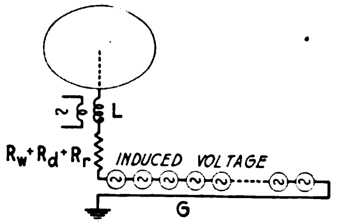

FIG. 8

Let us now consider the simple receiving circuit shown in Fig. 8. This circuit consists of an elevated capacity network, A, a tuning inductance, L, and a detector which has a resistance R_d. The capacitance of the network to ground is represented by C. In addition to the detector resistance the circuit has a wasteful resistance, R_w, and a radiation resistance, R_r. The induced voltage is represented by the group of generators, G. If this station is to receive I. C. W. signals, the characteristics of the generators have already been found. We wish to design the circuit so that it will approach as nearly as possible the ideal receiver described above.

It is, of course, impossible to adjust this circuit so that it will act as a pure resistance to all of the generators lying in the band $n = 0$ to $n = \pm n_r$ and to eliminate the currents due to all of the other generators. We will therefore tune it to the frequency f_0.

Now the number of cycles by which the nth generator is removed from f_0, is $\frac{n}{2T}$. It can be shown that the net reactance of the circuit to the nth generator is:

$$x_n = 2 \pi L \frac{n}{T} \quad (9)$$

Let us now assume that, in order to have the circuit respond to as few frequencies as possible and still have the signals discernible, the reactance to the n_r generator should be equal to βR_t. From (9) we arrive at

$$\frac{L}{R_t} = \frac{T_c}{2} = \frac{\beta T}{2 \pi n_r} \quad (10)$$

T_c is the time constant of the antenna circuit.

$$x_n = \beta R_t \frac{n}{n_r} \quad (11)$$

If we let the detector resistance be

$$R_d = \rho (R_r + R_w) \quad (12)$$

and let

$$K = \frac{R_r + R_w}{R_r} \quad (13)$$

then the average power delivered to the detector is

$$P = \frac{E^2 \rho}{2 k R_r (1 + \rho)^2} \left[\frac{1}{4} + \frac{2}{\pi^2} \sum \frac{1}{n^2\left(1 + \beta^2 \frac{n^2}{n_r^2}\right)} \right]$$

$n = 1, 3, 5$ etc.

If this circuit is used with the same antenna as the ideal circuit, the power available is again given by Equation (7).

Estimations based upon the shape of the antenna current wave and also upon the time constant of the circuit show that when $n_r = 3$, β should equal about 2.

If these values are assigned to n_r and β and if ρ is assigned the best value, (namely unity,) the ratio of the power utilized by the simple series receiver to the power available is,

$$\frac{P}{P_a} = \frac{0.8}{k} \quad (15)$$

4. *Spark Telegraphy.* The voltage induced in a receiving antenna by a spark transmitting station is assumed to have the form shown, schematically, in Fig. 9. The operating frequency is $f_0 = \frac{\omega}{2\pi}$. In most spark systems the damping is such that the voltage

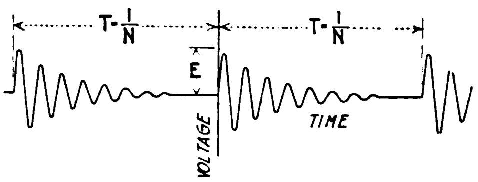

FIG. 9

dies very nearly to zero in the interval of time, T, ($\alpha T > 3$). Under these conditions the voltage is represented as a function of time during the interval $t = - T$ to $t = 0$ by the equation

$$e(t) = E \epsilon^{-\alpha(t+T)} \sin [\omega (t + T)] \quad (16)$$

and in the interval $t = 0$ to $t = + T$ by

$$e(t) = E \epsilon^{-\alpha t} \sin \omega t \quad (17)$$

It can be shown that B_n is stated very closely by the

equation:

$$B_n = \frac{2E}{\omega T} \frac{1}{\sqrt{\frac{4\ \alpha^2}{\omega^2} + \left[\frac{2\ n}{f_0\ T} + \frac{n^2}{f_0^2\ T^2}\right]^2}} \qquad (18)$$

$$n = 0, \pm 1, \pm 2 \ldots \ldots \begin{matrix} + \infty \\ \\ - f_0 T \end{matrix}$$

In this equation the symbols have the following meaning:

B_n is the voltage of the generator with frequency differing from f_0 by $\frac{n}{T}$ cycles per sec.

f_0 is the operating frequency of the spark-transmitting station.

E and α are defined by Equation (**17**).

$\omega = 2\,\pi\,f_0$

T is the time duration in seconds of each spark.

Let

$N = \frac{1}{T}$ represent the number of sparks per second.

$\delta = \frac{\alpha}{f_0}$ represent the logarithmic decrement.

In terms of these symbols (**18**) becomes

$$B_n = \frac{2\ N\ E}{\omega} \frac{1}{\sqrt{\frac{\delta^2}{\pi^2} + \left[\frac{2\ n\ N}{f_0} + \frac{n^2\ N^2}{f_0^2}\right]^2}} \qquad (19)$$

The voltage of the generator having a frequency the same as the operating frequency f_0 is:

$$B_0 = \frac{E}{\alpha\ T} = \frac{N\ E}{\alpha} = \frac{N\ E}{\delta\ f_0} \qquad (20)$$

In order to present at a glance the way in which the generator voltage varies with the frequency in the vicinity of the operating frequency, f_0, and the effect of the logarithmic decrement, δ, the number of sparks per second, N and the operating frequency on this variation, the curves of Fig. 10 have been drawn. The abscissa for all curves are values of the difference between the generator frequency and the operating frequency ($= n\,N$). Generator frequencies are located only at integral values of $n\,N$ divided by N. Thus at 1000 sparks per second, one generator has the frequency f_0 and the generators are located on a frequency scale every 1000 cycles per second above or below f_0. At 120 sparks per second generators are located on the frequency scale at f_0 and every 120 cycles per second above or below f_0. For curve (1) $f_0 = 10^6$ cycles per second, $\delta = 0.01$, $\alpha = \delta\,f_0 = 10^4$, $N = 1000$. The ordinates for this curve are values of the ratio of the generator voltage to the undamped peak voltage, E_1, induced in the antenna. $\left(\text{Ordinates are values of } \frac{B_n}{E_1}\right)$. The voltage assigned to the generators falls off at a fairly fast rate as the operating frequency is departed from. The generator, having a frequency which differs by 16,000 cycles per second from the operating frequency, has a voltage 10 per cent as great as the voltage of the generator with a frequency equal to the operating frequency. That is, the energy associated with a frequency removed from the operating frequency by 16,000 cycles per second is one per cent as great as the energy associated with the operating frequency. This curve also holds good for the conditions $f_0 = 10^5$, $N = 1000$, $\delta = 0.1$, $\alpha = \delta\,f_0 = 10^4$. This fact has an important bearing on the factors which determine the frequency-energy distribution as will be shown a little later.

For curve (2) $f_0 = 10$, $N = 1000$, $\delta = 0.1$, $\alpha = \delta\,f_0 = 10^5$. In order to make this curve directly comparable with curve (1), the ordinates have been taken as values of the generator voltage divided by the undamped voltage peak induced in the antenna by case (1) when both sets of waves have the same energy per wave train or per spark. That is the ordinates in this case are values of $\frac{B_n}{E_2}$ multiplied by $\sqrt{\frac{\alpha.}{\alpha_1}}$*. This curve is much flatter than curve (1) and the generator with frequency removed from f_0 by 16,000 cycles per second, has a voltage 70 per cent as great as the voltage of the generator whose frequency is f_0. This is a striking contrast to curve (1) for which $\alpha = 10^4$.

For curve (3) $f_0 = 10^6 \sim$, $N_2 = 120$, $\delta = 0.01$, $\alpha = 10^4$. The ordinates for this curve are values of $(B_n/E_3)\sqrt{\frac{N_1}{N_2}}$†. This factor is used in order to compare this case with case (1) when both waves have the same energy associated with them. The rate at which the generator voltage falls off in this case with the frequency is about the same as for case 1. This curve is also valid for the conditions $f_0 = 10^5 \sim$, $N = 120$, $\delta = 0.1$, $\alpha = 10^4$.

These curves lead to the conclusion that the factor which determines the rate at which the generator voltages fall off with the frequency in the vicinity of f_0, is $\alpha = \delta\,f_0$. The other factors have but little influence upon the width of the band of frequencies over which most of the energy is spread. This is apparent upon examining equations (**18**) or (**19**).

When n is small, the second term in the bracket under the radical is small compared to the first and may be

*See the discussion of energy relations which follows shortly.
†See the discussion of energy relations which follows shortly.

dropped without serious error. We then have for small values of n,

$$B_n = \frac{E\,N}{\sqrt{\alpha^2 + 4\,\pi^2\,n^2\,N^2}} \qquad \textbf{(20a)}$$

This equation shows clearly the dependance of the band width upon α, because the larger the value of α the larger must be the $n\,N$ product before B_n differs much from B_0.

The ideal system for receiving spark signals has the same properties as the ideal system for receiving I. C. W. signals except that the transmitted band width will be different. In so far as obtaining a good tone in

the receivers is concerned, it would suffice to pass only the currents of three generators; this would, however, result in the utilizing of only a small portion of the available energy. Let us therefore make the band wide enough to pass the currents of all generators with voltage equal to or greater than r decimal parts of the voltage of the generator the frequency of which is f_0. From equations (20) and (**20a**) we than have

$$\frac{B_{nr}}{B_0} = \frac{\alpha}{\sqrt{\alpha^2 + 4\,\pi^2\,n_r{}^2\,N^2}} = r \qquad \textbf{(20b)}$$

$$n_r\,N = f_c = \frac{\alpha}{2\,\pi}\sqrt{\frac{1}{r^2} - 1} \qquad \textbf{(20c)}$$

Since n_r must be an integer it is taken as the integer which comes the closest to satisfying (**20c**). $n_r\,N = f_c$ is then one-half of the transmitted band width.

It can be shown that the power available in the damped waves is:

$$P_a = R_r\,I_a{}^2 = \frac{N\,E^2}{16\,\alpha\,R_r} \qquad \textbf{(21)}$$

P_a as given by (**21**) represents the power available in the waves. Since this power varies directly as E^2, directly as N and inversely as α, it is evident that the correction factors applied to the curves of Fig. 10 are the proper ones.

The average power picked up and utilized by the ideal receiver from the waves sent out by a spark transmitter is given by the relation:

$$P = \frac{E^2\,N^2}{8\,R_r}\left[\frac{1}{\alpha^2} + 2\sum_{n=1}^{n_r}\frac{1}{\alpha^2 + 4\,\pi^2\,n^2\,N^2}\right] \qquad \textbf{(22)}$$

If the damping exponent, α, of the waves has value of 10^4 and if r is taken to be 0.3, then the half band width as given (**20c**) is:

$$f_0 = n_r\,N = \frac{10^4}{2\,\pi}\sqrt{11.1 - 1} = 5000 \sim \qquad \textbf{(23)}$$

If the number of sparks per second N is 1000, $n_r = 5$ and the ratio of the power utilized by the ideal receiver to the power available is 0.82.

If the receiving system consists of a simple series circuit, the general discussion given under the I. C. W. case still applies. In the present case, the number of cycles by which any generator frequency differs from the resonant frequency of the system is $n\,N$.

If the reactance of the circuit to the frequency $n_r\,N$ is to equal $\beta\,R_t$ we have:

$$\frac{L}{R_t} = \frac{T_c}{2} = \frac{\beta}{4\,\pi\,n_r\,N} \qquad \textbf{(24)}$$

Equation (**24**) is analogous to equation (**10**) of the I. C. W. case and fixes the freely transmitted band. The net reactance now becomes:

$$x_n = \beta\,R_t\,\frac{n}{n_r} \qquad \textbf{(25)}$$

The average power supplied to the detector of the simple series receiving circuit by the damped waves is,

$$P = \frac{E^2\,N^2\,\rho}{2\,k\,R_r\,(1 + \rho)^2}\left[\frac{1}{\alpha^2} + 2\sum_n\frac{1}{(\alpha^2 + 4\,\pi^2\,n^2\,N^2)\left(1 + \beta^2\,\frac{n^2}{n_r{}^2}\right)}\right] \qquad \textbf{(26)}$$

If there are 1000 sparks per second and if $\alpha = 10^4$ and $n_r = 5$, $\beta = 2$ and $\rho = 1$ then the ratio of the power

utilized by the simple series receiver to the power available in the waves is:

$$\frac{P}{P_a} = \frac{0.6}{k} \tag{27}$$

Equations (**26**) and (**21**) show that for a given transmitted band width, the ratio of the power utilized to the power available becomes smaller as the damping exponent, α, is increased. This is because the greater the value of α the wider is the frequency band over which the energy is distributed.

5. TELEPHONY

The voltage of the generators which may be inserted in the receiving system to replace the voltage induced in the antenna by a radio telephone transmitter can not be written down in a general equation because it depends upon the character of the speech or music which is being sent out. The theory of modulation however shows that the voltage induced in the antenna of the receiving system has a group of frequencies consisting of the carrier frequency, an upper side band, and a lower side band. The carrier frequency is the operating frequency and determines the wave length of the transmitting station. The upper side band consists of a group of frequencies having values equal to the carrier frequency plus the frequencies of the voice or musical notes. The lower side band consists of a group of frequencies having values equal to the carrier frequency minus the frequencies of the voice or musical notes. If the highest musical note of importance is represented by f_c, then, in radio telephony, most of the energy is associated with a band of frequencies $2 f_c$ cycles wide, centered on the carrier or operating frequency, f_0. If only a small portion of the energy is associated with frequencies outside this band, then we may replace the voltage induced in the receiving system by a group of generators having frequencies ranging from $f_0 - f_c$ cycles per second to $f_0 + f_c$ cycles per second. The voltage assigned to a generator having a given frequency will depend upon the nature of the speech or the music which is being received.

The ideal frequency selection system for receiving telephony will have the same properties as the ideal system described for the reception of I. C. W. signals with the exception that it must transmit freely the currents due to all generators having frequencies in the band $f_0 \pm f_c$ cycles per second. This ideal system would utilize practically all of the available energy and would be distortionless. The highest violin note of much importance has a frequency of about 5000 cycles per second. Therefore, for broadcast reception, it suffices to take f_c equal to 5000 cycles per second and the ideal receiver must transmit freely a band of frequencies 10,000 cycles wide centered on the operating frequency f_0.

It is impossible to design the simple series receiving circuit so that it will have no distortion and maintain good selectivity against interference. In the amplifying systems and in the loud speakers used for broadcast reception there is a good deal of distortion and the simple series circuit need not be freer from distortion than the rest of the system. The general discussion of the simple series receiver given under the I. C. W. case and the spark case applies here. If the system is tuned to the carrier frequency, then, from equation (**9**), the reactance of the system to the frequency $f_0 \pm p$ is given by the relation:

$$x_n = 4 \pi L p \tag{28}$$

If the reactance of the system to the generator whose frequency is $f_0 \pm f_c$ is βR_t then (**62**) may be written as:

$$x_n = \beta R_t \frac{p}{f_c} \tag{29}$$

If the r. m. s. value of the voltage of the generator

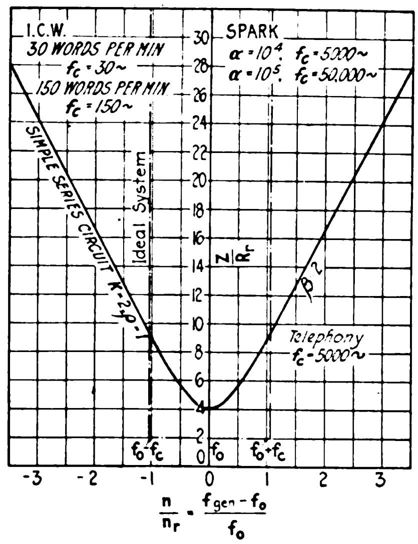

FIG. 11—TRANSMISSION CHARACTERISTICS

having a frequency of $f_0 \pm p$ is E_p the power delivered to the detector by the telephonic waves is,

$$P = \frac{\rho}{k R_r (1 + \rho)^2} \left[E_0^2 + 2 \sum_p \frac{E_p^2}{1 + \beta^2 \frac{p^2}{f_c^2}} \right] \tag{30}$$

The average power received from the generator with a frequency of $f_0 \pm f_c$ is:

$$P_c = \frac{E_c^2 R_d}{R_t^2 (1 + \beta^2)} \tag{31}$$

For distortionless reception this power should be:

$$P_{c1} = \frac{E_c^2 R_d}{R_t^2} \tag{32}$$

We may then take, as a measure of the distortion, the ratio of P_c to P_{c1}. This ratio is,

$$D = \frac{P_c}{P_{c1}} = \frac{1}{1 + \beta^2} \tag{33}$$

If β is taken equal to 2, the highest important voice or musical note will have one-fifth the energy it should

have for distortionless reception. With the distortion as great as it is in the rest of the receiving equipment, this amount will probably not be excessive.

Since the ideal receiving system and the simple series receiving system are the same with the exception of the width of the transmitted band for all the three types of signals considered, it is possible to plot a single transmission characteristic for each one, to hold for all three types of signals. Such curves are plotted in Fig. 11. The abscissa scale is the ratio of the difference in generator frequency and the operating frequency to the cut off frequency f_c. The ordinate scale is the ratio of Z to R_r. Z is the ratio of the generator voltage to the detector current which has the same frequency as the generator voltage under consideration. The transmission characteristic of the simple series circuit is plotted for a value of β equal to 2 and for the best possible values of k and ρ. These curves show at a glance, the degree to which the simple series receiver falls short of the ideal receiver. These curves will be discussed more fully in the sections dealing with the reception through interference.

Part II.—Reception Through Interference

6. Voltage Induced in Receiving Antenna by Static

The voltage induced in a receiving station by an I. C. W., a spark, or a telephone transmitter may be a source of interference as well as of signals. The frequency and voltage of the generator which may be used to replace these voltages in the receiving system have already been worked out. This section will be devoted to a discussion of the generators which represent the voltage induced in the receiving system by atmospheric strays or static. There is not very much information available on the wave form of the voltages induced in antennas by static. Watt and Appleton have published some observed static wave forms in the Proceedings of the Royal Society, 1923. These wave forms were sketched from visual observations made with a Braun tube oscillograph. The majority of the impulses were unidirectional in character and the time of rise and fall was about the same. The time duration of the majority of the impulses was of the order of one thousandth of a second. It is reasonable to expect then that some indication of the voltage and the frequency of the generators which replace the static voltage in the receiving antenna will be obtained if the wave form of the voltage induced by static is assumed as shown by Fig. 12. The Fourier expansion of this wave form leads to the following general conclusions relative to the generators which replace the voltage induced in a receiving antenna by static.

1. The voltage assigned to a generator having a high frequency is less than the voltage assigned to a generator having a lower frequency.
2. The voltage assigned to all of the generators having frequencies which lie in a narrow band in the radio range of frequencies will be about the same.

In regard to assumption No. 1, it may be stated that the wave form assumed indicated that the voltage assigned to a generator was inversely proportional to the square of the frequency assigned to it.

If a voltage wave form having an abrupt rise, a flat top and an abrupt fall had been assumed, then the voltage assigned to a generator would be inversely proportional to the first power of the assigned frequency. Therefore, if the indications of the Watt and Appleton

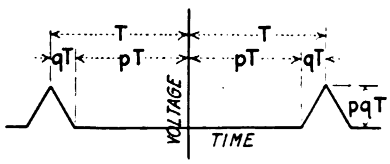

Fig. 12

observations on the time duration of the impulses are anywhere nearly correct, the voltage assigned to a generator will vary inversely as a power of the frequency which lies between 1 and 2.

7. The Reception of I. C. W. Signals Through Static Interference

The receiving system is represented schematically as shown in Fig. 5, and we now have to consider the power received from two groups of alternators. One group of alternators replaces the voltage induced in the antenna by the I. C. W. transmitting station. The other group replaces the voltage induced in the receiving antenna by static. Since the voltage assigned to all the static generators whose frequencies lie in a narrow band is the same we will let E_s be the peak value of the voltage of each static generator. If the generator frequencies are spaced p cycles per second apart on a frequency scale, the power delivered by static to the ideal receiver is,

$$P_s = \frac{2 f_c}{p} \frac{E_s^2}{8 R_r} = \frac{n_r}{p T} \frac{E_s^2}{8 R_r} \qquad (34)$$

From equations (8) and (34), we obtain for the I. C. W. signal power-static, power ratio of the ideal receiver

$$\frac{P_{i.c.w.}}{P_s} = \frac{E^2 p T}{E_s^2} \frac{1}{n_r} \left[\frac{1}{4} + \frac{2}{\pi^2} \sum_s \frac{1}{s^2} \right]$$

$$= \frac{E^2 p}{2 E_s^2 f_c} \left[\frac{1}{4} + \frac{2}{\pi^2} \sum_s \frac{1}{s^2} \right] \qquad (35)$$

$$s = 1, 3, 5 \ldots n_r$$

In equation (35) $\dfrac{E_s^2}{p}$ characterizes the static energy level associated with frequencies in the vicinity of the operating frequency f_0 of the I. C. W. station. This term varies from time to time and decreases as f_0

increases. $E^2\left[\frac{1}{4}+\frac{2}{\pi^2}\sum\frac{1}{s^2}\right]$ characterizes the I. C. W. signal energy level and its distribution over frequencies in the vicinity of f_0. The bracketed term is the same for all I. C. W. stations but E is dependent upon the transmitting station and the transmission efficiency. T characterizes the speed of signaling its value decreasing directly with an increase in signaling speed. Thus the high signaling speeds are more subject to static interference than the low ones. n_r alone characterizes the receiving system. For the ideal receiver n_r has been assigned the minimum value which will permit of the distinguishing of the signals. Thus the ideal receiver reduces the static interference to the lowest possible value that can be obtained with a frequency selecting system.

If the speed of transmission is 30 words per minute and if $n_r = 3$ we have:

$$\frac{P_{i.c.w.}}{P_s} = \frac{E^2\,p}{E_s^{\,2}}\,(0.008) \tag{36}$$

At 150 words per minute, the ratio will be one-fifth as large as at 30 words per minute.

The mathematical formulation of the interference in actual receiving systems is left for a future paper, but it can be pointed out that, for the simple series receiver, the best signal-power, static-power ratio is obtained when f_c is assigned as small a value and β as large a value as possible and yet have the signals distinguishable. This follows because decreasing β or increasing f_c permits the generators removed from f_0 to furnish more power to the circuit. But as shown by the curve of Fig. 7 the voltage of the signal generators falls off rapidly as their frequency departs from the operating frequency whereas it has been shown that the voltage of the static generators remains about the same at all of the frequencies. Therefore, increasing f_c or decreasing β, that is decreasing the time constant of the circuit, increases the static power faster than the interferent power. From this it is apparent that the simple series receiver described is the best possible one for receiving through static.

8. The Reception of Radio Telephone Signals Through Static Interference

In the section on telephone reception it was shown that for distortionless reception the ideal receiving system must pass a band of frequencies running from $f_0 - f_c$ cycles per second to $f_0 + f_c$ cycles per second where f_c was about 5000 cycles. Under these conditions the static power picked up by the system is given by equation (**34**). Since the ideal system picks up energy only from generators which have frequencies lying in the band which must be transmitted, it is evident that the ideal system as described is the best possible frequency-selection system for receiving telephone messages through static interference. Since f_c for telephony is $5000 \div 30 = 167$ times as large as for I. C. W. reception at 30 words per minute, it is evident that 167 times as much static energy must be picked up in a telephone receiver as in an I. C. W. receiver.

The extent to which static interference can be reduced by the simple series circuit depends upon the allowable distortion of speech or music. In plotting the transmission characteristic of the simple series circuit given by Fig. 11, it was assumed that the energy in the 5000-cycle voice or musical note could be reduced to one-fifth of the value which it should have for distortionless reception. ($\beta = 2, f_c = 5000 \sim$).

9. The I. C. W. Transmitter and the Spark Transmitter as Sources of Interference

It has been shown that the voltage induced in a receiving antenna by an I. C. W. transmitter could be replaced by a group of generators having the correct frequencies and correct voltages. Any I. C. W. transmitting station has generators with frequencies located in all frequency bands. It has also been shown that all receiving systems must transmit a band of frequencies centered upon the operating frequency of the station whose signals it is desired to receive. The receiving system must necessarily therefore pick up energy from all I. C. W. stations which induce a voltage in the receiving antenna. With a given receiving system the energy picked up from an interferent I. C. W. station depends upon the difference between the operating frequency of the interferent station and the operating frequency of the correspondent station and the manner in which the voltage assigned to any generator which replaces the interferent voltage in the receiving antenna vary with the frequency assigned to it. The curve of Fig. 7 gives a graphical picture of the dependance of the voltage assigned to any generator upon the frequency assigned to the generator. For I. C. W. telegraphy at 30 words per minute 90 per cent of the energy in the waves is associated with a band of frequencies 60 cycles wide centered on the operating frequency. At 150 words per minute the band containing 90 per cent of the energy is five times this wide. We thus come to the conclusions that the energy associated with the waves of an I. C. W. transmitter is confined to a narrow band of frequencies and the width of this band varies directly with the signal speed. The above statement holds true if the I. C. W. transmitter has no harmonics. If harmonics are present in the waves sent out by the transmitter, the voltages assigned to generators having frequencies in the vicinity of the harmonic will vary as shown by Fig. 7 for the fundamental frequency and any receiving station having a transmitted band in the vicinity of one of the harmonics will pick up an appreciable amount of power from the transmitter.

The spark transmitter causes much more interference than the I. C. W. transmitter. This fact is brought out in a striking manner if the curves of Fig. 10 are compared with those of Fig. 7. The voltage assigned to a generator falls off slowly as the frequency departs

from the operating frequency. From an examination of the curves of Fig. 10 and from the discussion of section (4) it is evident that the interference caused by a spark station is dependent upon the logarithmic decrement times the frequency rather than upon the logarithmic decrement. If $\alpha = \delta f_0 = 10^4$, 82 per cent of the energy in the waves is associated with a band of frequencies 10,000 cycles wide, centered on the operating frequency f_0. If $\alpha = \delta f_0 = 10^5$, then 82 per cent of the energy is associated with a band of frequencies approximately 100,000 cycles wide, centered on the operating frequency. This is in striking contrast to the I. C. W. case where most of the energy is associated with a band of frequencies 60 to 300 cycles wide. From the above discussion it is evident that a station operating at a frequency of 10^6 cycles per second, and having a logarithmic decrement of 0.01, has its energy spread over the same band width as a station operating at 10^5 cycles per second and having a logarithmic decrement equal to 0.1.

10. General Conclusions

With regard to the extent to which interference can be mitigated by frequency selecting systems all sources of interference to radio reception and all sources of signals have a definite frequency spectra and for convenience we can replace the voltages induced in an antenna by a group of generators having the correct voltages and frequencies. In order to receive signals the receiving system must pass freely the currents due to all generators having frequencies in a given band. This band is centered on the operating frequency of the station from which it is desired to receive signals. The width of the band is determined by the class of signals which it is desired to receive. If the interferent voltages have generators with frequencies in this transmitted band, the frequency selection system cannot eliminate the currents due to these generators. Since the ideal receiver as specified in this paper utilizes the maximum possible power from generators lying within the band of frequencies which must be passed and utilizes no power from generators which have frequencies outside this band, it is evident that the interference obtained in the ideal receiver is the minimum which can be obtained with frequency selecting systems. From this it is evident that the minimum interference which is obtainable depends upon the ratio of the voltage of the signal generators to the voltage of the interferent generators which lie in the transmitted band and upon the width of the band of frequencies which it is necessary to transmit. The width of the band of frequencies which must be transmitted depends upon the class of signals which are to be received. Thus while the necessary transmitted band width for I. C. W. telegraphy at 30 words per minute is only 60 cycles, at 150 words per minute it is 300 cycles. The necessary transmitted band width for telephony is about 10,000 cycles and the necessary transmitted band width for spark telegraphy varies from 10,000 cycles to 100,000 cycles depending upon the product of the logarithmic decrement times the operating frequency.

The ideal receiving system thus furnishes a criterion by which we can judge of the merits of any actual frequency selection system for receiving through interference. The writer hopes in a future paper to show how near actual receiving systems of various types approximate the ideal receiver.

Research

Report of Technical Committee on Research*

J. B. WHITEHEAD, Chairman

To the Board of Directors:

The year just closing has revealed the usual activity in the field of electrical engineering research. This activity extends from laboratory investigations of purely scientific character, outward to the development of all equipment, and to the study and improvement of the performance of the largest types of machinery and transmission systems. The importance of scientific research to industry in all its branches is now clearly recognized. The idea of research is "sold". Moreover, it appears to have been a bargain based on good value, for the article sold is in constant use and there is increasing demand for it. Industrial research laboratories are numbered by hundreds. Problems demanding solution are continually appearing, and there is increasing need for skilled research workers.

The National Research Endowment

There has, however, been one new and striking note during the year which has immediate bearing on the future of engineering research. This is the shifting of the emphasis in public discussion from the importance of applied and industrial research to the importance of protecting and stimulating purely scientific research. Advocates of the value of industrial research have

Presented at the Annual Convention of the A. I. E. E. at White Sulphur Springs, W. Va., June 21-25, 1926.

always pointed to its intimate dependence on a fundamental scientific basis. Industrial research laboratories have realized from their beginnings their dependence upon trained research workers. Recently, however, Secretary Hoover has pointed out that the tremendous development of industrial research has resulted in two tendencies which threaten to dry up the sources of inspiration for research, and to diminish the number of those who are fitted to carry it on. The first of these is the stripping of university laboratories of their men who are trained in research because of attractive offers from industrial laboratories. The second is the great increase in university student attendance which has compelled universities to limit research activities in order to meet the mere volume demand for elementary education. Recognizing this tendency, Secretary Hoover has placed the weight of his great influence back of the suggestion of the National Academy of Sciences that a national research endowment be accumulated, whose chief purpose should be the promotion of purely scientific investigation in American universities, the natural nurseries for the training of competent scientific research workers. As a result Herbert Hoover, Elihu Root, Chas. E. Hughes, Owen D. Young, John J. Carty, Wm. H. Welch, and other distinguished associates are serving as trustees of the National Research Endowment, whose purpose is to raise twenty million dollars to aid American universities in carrying on fundamental research during the next ten years.

This movement is one of the healthiest and most promising events in recent years for the further development and progress of research in all fields of industry. Not only will it tend to conserve the sources of supply of research workers, but it is certain to result in an elevation in the general standards of ability, and in the increase of researches of scientific value, emanating not only from universities but also from industrial research laboratories. Industry itself has been quick to recognize the importance of the move, for the heads of many great corporations have entered actively into the campaign to raise the endowment, and it is not unlikely that industry itself will make substantial contributions.

Electrical Engineering Research

Naturally electrical engineering with its rapid development and expansion, its dependence on physical laws only uncovered in recent years, is always a heavy contributor in the field of engineering research. While there is no single result of outstanding novelty and importance, the past year has nevertheless seen many advances of interest. The range of problems studied has been much the same, but some shifting of emphasis in the various fields may be noted. Thus, for example, in overhead high-voltage transmission, attention has centered more particularly on analytical studies of the regulation, stability, and power limitations of high lines and large systems. At the same time there has been somewhat less attention than in foregoing years to experimental studies, in laboratory and field, of transients, protective apparatus, and high-voltage problems, although these have continued in some measure. The laws of corona, its physical character, and its bearing on transmission-line performance are still unanswered questions, and are therefore receiving some attention.

In the field of electrical machinery the intensive study devoted to fuel economy, with the resulting improvements in steam-power producing machinery, is so striking as to warrant its inclusion here as an important research activity. More directly in the analytical and laboratory class are continued studies of the problem of the ventilation of large rotating units, and of the general relations between temperature and machine rating. Other studies of note are in connection with machinery and the application of delicate vibrating instruments to problems of balance, and the like, the mathematical similarity between mechanical and electrical systems, and the proposal to investigate the former electrically through the equivalent investigation of the mechanical forces arising in short circuits in synchronous machinery. There have been fewer papers than usual on the properties of iron as related to the question of core losses.

There has been a continuation of the marked activity in experimental studies in the field of electric communication. Papers have been presented to the Institute reporting studies of the quality, the recording, and the reproducing of sound, on the importance of loading telephone circuits, and on new methods of carrier-current transmission. The publications of the Bell Telephone Laboratories show an extremely wide range of subject of investigation. Some of them are scientific research of the purest character, and the range extends to the experimental development of equipment and methods for meeting the increasing modern demands for facility in communication.

Results in the radio field are numerous and important. New tubes are being developed, new circuits devised, and new methods adopted for improvement in all directions of this highly specialized branch of electrical engineering. Perhaps the most interesting activity has been that of studying the behavior of short-wave transmission and the resulting new knowledge that has come as to the conducting properties of the upper atmosphere.

In the field of electrical measurements, among other noteworthy advances, may be mentioned the adaptation of the cathode ray oscillograph to the measurement of very short-time intervals, simpler and more convenient forms of oscillograph, and a greatly increased attention to the methods of measurement of dielectric loss at low-power factor and high voltage.

Studies which lie close to the field of pure physical research, and which may prove to have a practical bearing, are those in which the cathode stream of electrons has been brought through the walls of the tube into the surrounding air, the study of atomic hydrogen in its adaptation to arc welding, the obtaining of copper in large crystals showing 13 per cent increase in normal

conductivity, and the continued study of the structure of crystals by the means of X-rays.

Dielectrics and Insulation

The Committee on Research has continued to devote its principal attention to the subject of dielectrics and insulation. It serves as a consulting committee in Electrical Engineering to the National Research Council. Several of its members are also members of the Committee on Electrical Insulation of the Division of Engineering and Industrial Research of the National Research Council, the two committees having the same chairman. The program of the Committee on Electrical Insulation has been outlined in foregoing reports. During the past year considerable progress has been made by the subcommittees in the respective divisions. The Subcommittee on Dielectric Absorption and Theories of Dielectric Behavior has made a report which was also presented at the Midwinter Convention of the Institute. It is a comprehensive survey of existing knowledge of the anomalous properties of dielectrics and of theories that have been offered in explanation, and it includes suggestions of directions in which further experiment will probably result in new knowledge important to the control of the properties of insulation. As a result of this report the Committee on Electrical Insulation is prepared to suggest problems for investigation and research. It also hopes that some plan may be worked out whereby joint and coordinated work of a number of investigators may be undertaken. The report of the subcommittee on Dielectric Strength may be expected in the near future. The literature on these subjects is very extensive, and requires careful reading and discrimination. The members of the Committee are giving their services voluntarily and this work of necessity takes a secondary place in their busy programs.

The Committee is glad to record continued activity in the experimental investigation of the properties of insulating materials of all characters, and believes that its own interest in this field of study has stimulated the interest which lies back of the present activity. During the year there have been presented to the Institute important papers on gaseous ionization in paper-insulated cables, on the theory of dielectric absorption, the measurement of dielectric losses, and a method for the convenient and quick measurement for the absorption in commercial insulation. Attention should also be called to important contributions from abroad. A noteworthy paper on high-voltage, impregnated-paper cables has appeared in England, and there have been a number of papers from Germany bearing on the dielectric strength of different materials with special reference to the mechanism of the failure of high-voltage insulation.

Organized Research

It is a conspicuous feature of research activity in general that it is highly organized in industrial laboratories, but proceeds practically without organization in university laboratories. This situation is natural. The work in an industrial laboratory is usually directed towards the solution of particular questions, and if they are sufficiently important the whole resources of the laboratory may be diverted to their solution. In university laboratories individual workers find such time as they can for research outside of crowded programs, and usually do research without material compensation and only for the love of it.

Considering both extremes it will be seen that the situation is not particularly conducive to the production and publication of important results of research. In a few notable instances industrial research laboratories are making substantial efforts in the field of pure physical research, and it is possible to point to results of great value emanating from these efforts. These examples are few, however, and on the whole it can not be said that results of fundamental scientific value are to be expected in large quantities from laboratories in this class. In only a few university laboratories is any considerable proportion of the resources of men and materials devoted to original investigation. Such as is accomplished usually comes from men who are willing to sacrifice time outside the educational program, and who are prompted to it solely by the love of it.

An exceptional and promising example of organized research is that being carried out at Harvard, Johns Hopkins, Massachusetts Institute of Technology, and the University of Wisconsin, on the impregnated-paper insulation of high-voltage cables. The work is being done under the auspices of the Committee on Cable Insulation Research of the National Electric Light Association, whose member companies have subscribed sufficient funds to ensure the active prosecution of the work. Results of importance and value are already beginning to appear.

It would appear, then, that the several national organizations which have among their principal purposes the encouragement and support of engineering research, might do well to undertake actively the organization of research in university laboratories and the provision of material support of the necessary experienced research workers. The national engineering societies might consider also with propriety, these things as lying among their normal functions. The National Research Endowment is pledged specifically to support pure scientific research in university laboratories. There are some problems of pure research which must be attacked by research engineers, but it appears doubtful whether appeal for work in the engineering field will for sometime receive consideration by the National Research Endowment. It is highly desirable, therefore, that engineering foundations interested in research and the national engineering societies should consider how the sources of the training of research engineers can best be conserved, and how activity in engineering research may be encouraged.

Accuracy Required in the Measurement of Dielectric Power Factor of Impregnated Paper-Insulated Cables

BY C. F. HANSON[1]

Member, A. I. E. E.

Synopsis.—*This paper deals with the effect of errors in the measurement of power factor upon the usefulness of impregnated paper-insulated cables. It points to error in the knowledge of the thermal properties of the cable and the cable duct. The latter error affects the usefulness of a cable to such an extent as to permit a limited error in the power factor without materially reducing the efficiency of the cable. This limited error defines the required power-factor accuracy.*

The required power-factor accuracy in general is found to vary directly with the frequency and the specific inductive capacity of the insulation, and to increase with the number of cables in a duct bank and the ratio of E^2/G, where E is the operating voltage of the cable in kilovolts and G is the geometric factor. For very high-voltage single-conductor cables the power-factor accuracy should be within the order of 0.002.

* * * * *

Introduction

The significance of an error in the measurement of one property of a commodity depends upon the limitations which that error imposes upon the usefulness of the commodity. At first hand, it would seem that this error should be reduced to as low a value as possible in order that the commodity may have a maximum usefulness. However, in the measurements of other properties of the commodity, errors exist which also impose limitations. An error in the measurement of the property, therefore, need not be made as small as possible, but need be reduced only to a value which will impose very little additional limitations upon the usefulness of the commodity.

The purpose of this paper is to determine the significance of an error in the measurement of the dielectric power factor of impregnated-paper insulated cables. The method of attack lies in an endeavor to compare the power-factor error with the error existing in the knowledge of the thermal properties of the cable. This comparison is based upon the effect of each of these errors on cable efficiency. The efficiency of a cable is measured by its capacity to carry current.

No economic gain of any consequence can be realized by reducing power-factor error below a certain limit as long as errors exist in the thermal data of the cable and the cable duct. In other words, for a given accuracy in the thermal data, an appreciable gain in cable efficiency can be realized by increasing power-factor accuracy only up to a certain limit. This limit of power-factor accuracy can be defined, for the purpose of this paper, as the required power-factor accuracy.

If the accuracy of the thermal data should increase, then the required power-factor accuracy would likewise increase. To provide for this situation, it is shown how the latter varies with respect to the former. With this information available, the required power-factor accuracy can be determined and then compared with the estimated power-factor accuracy obtained in the measurements. If the estimated accuracy is less than the required accuracy, then the methods for measuring power factor should be improved. On the other hand, if the estimated power-factor accuracy is far in excess of the required, then the accuracy of the thermal data should be increased.

Three-Conductor Cable

The following formula gives the current-carrying capacity of a three-conductor cable:

$$I = \frac{18.08}{\sqrt{R}} \sqrt{\frac{T_0 - T_G}{R_{th}} - W_{DL}} \qquad (1)$$

This formula is practically the same as formula (24) given by Simons[2]. The term W_{DL} is the dielectric power loss in watts per foot of cable at 60 cycles, and is assumed, for the sake of simplicity, to originate on the surface of the conductors.

W_{DL} is proportional to the power factor $\cos \theta$.

- R = the resistance per conductor in ohms per 1000 ft. at the allowable temperature, T_0, in deg. cent. (two per cent is added for cabling).
- T_G = the base temperature of the earth in deg. cent. used as 20 deg. cent.
- R_{th} = thermal resistance between conductors and base in thermal ohms per foot of cable.
- I = current per conductor at the generator end of the cable in amperes.

The value of the current I is known with an accuracy of one per cent or better. The temperature, T_0, can be established under laboratory conditions with considerable accuracy. When T_0 is established, the value R becomes known to an accuracy within 2 per cent, the allowance required for manufacturing variation. The

1. Habirshaw Cable and Wire Corporation, Yonkers, New York.

Presented at the Regional Meeting of District No. 1 of the A. I. E. E., Niagara Falls, N. Y., May 26-28, 1926.

2. "Calculation of the Electrical Problems of Transmission by Underground Cables," Donald M. Simons, The *Electric Journal*, August, 1925, p. 375. To avoid confusion the author has used the same symbols as those used by Simons. The first published formula to include W_{DL} was given by Wm. A. Del Mar in Harold Pender's "Handbook for Electrical Engineers," 1922 edition, p. 2021.

accuracy of the terms T_G and R_{th} is low. These two terms need, therefore, be studied in considerable detail in trying to assign the accuracy required in power-factor measurements.

Simons' equation (**20**) gives the following expression for R_{th}

$$R_{th} = \frac{0.00522\,\rho\,G_1}{n} + \frac{0.00411\,B}{D} + N\,H \qquad (2)$$

ρ = thermal resistivity of insulation in watt-cm. units
G_1 = geometric factor of cable, all three conductor against sheath
n = number of conductors in the cable
B = surface thermal resistivity of lead sheath in watt-cm. units
D = outside diameter of the lead sheath in inches
H = heating constant of duct in thermal ohms per foot
N = number of similar cables in duct bank

The value of the fraction $\frac{T_0 - T_G}{R_{th}}$ can be varied either by assigning different values to T_G or to R_{th}. Any error existing in R_{th} can therefore, in equivalent terms, be added to the error existing in T_G. The foregoing fraction can therefore be rewritten into the following form in which ΔT_G is an equivalent error which combines the actual errors in T_G and R_{th}.

$$\frac{T_0 - (T_G \pm T_G)}{R_{th}}$$

The term W_{DL} contains an error of ΔW_{DL} and can therefore be written in the form $W_{DL} \pm \Delta W_{DL}$. Now, a certain equivalent error of ΔT_G in the base temperature of the earth will affect the value of I by the same amount as a certain error of ΔW_{DL}. Accordingly, the following equation can be written:

$$\Delta W_{DL} = \frac{\Delta T_G}{R_{th}} \qquad (3)$$

From Simon's formula (**17**) in the foregoing citation:

$$\cos\theta = \left(\frac{3144}{f\,k\,E^2/G_2}\right) W_{DL} \qquad (4)$$

E = Phase voltage in kilovolts
G_2 = Simon's geometric factor for three-phase operation
k = The specific inductive capacity and is taken to be 3.4
f = Frequency, and equals 60.

The power-factor error may be represented by $\Delta \cos \theta$ which corresponds to the dielectric power-loss error, ΔW_{DL}. Using these symbols in equation (**4**), the following relation is obtained:

$$\Delta\cos\theta = \left(\frac{15.4}{E^2/G_2}\right)\frac{\Delta T_G}{R_{th}} \qquad (5)$$

In calculating the value for R_{th}, the author has used 500 for the thermal resistivity of paper insulation in watt-cm. units. The surface thermal resistivity of lead sheath B in watts per cm. units, is 1200, the same as that used by Simons. The heating constant H of the duct in thermal ohms per foot is taken as unity in accordance with Simons and Atkinson.

Table I gives the power factor error, $\Delta \cos \theta$, caused by an equivalent error of 1 deg. cent. in the base temperature T_G for ten cables. $\Delta T_G = 1$ in formula (**5**). In this table, T is the conductor insulation thickness and t is the belt insulation thickness with both expressed in 64ths of an inch. The column of $\cos \theta$ gives what may be considered as a basic value of the power factor corresponding to the temperature T_0. To be sure, cables are manufactured having power factors less than those listed here, but on the other hand, cables are also made having higher power factors. In regard to operating voltage E, the table indicates an optimistic outlook on the performance of cables. The reason for this optimism is that the purpose of this survey is to consider power-factor measurements not only for cables being manufactured now, but also possible cables which may be manufactured during the next decade.

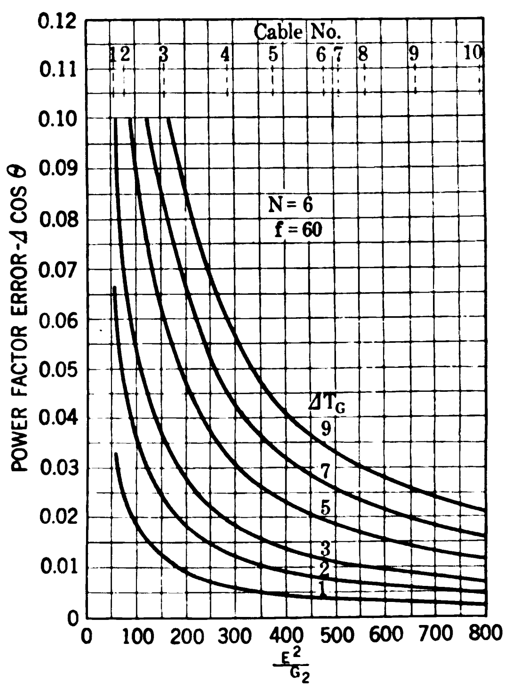

FIG. 1—POWER-FACTOR ERROR IN TERMS OF EQUIVALENT BASE TEMPERATURE ERROR $\Delta\ T_G$ FOR VARIOUS THREE-CONDUCTOR PAPER-INSULATED CABLES

The power factor error $\Delta \cos \theta$, is independent of the basic power-factor $\cos \theta$ according to formula (**5**). In other words, had other values been chosen for the basic power factor, $\cos \theta$, than those listed in the table, the power-factor errors, $\Delta \cos \theta$, would remain the same. This observation leads to an important conclusion. If the allowable power-factor error is limited only by errors existing in the base temperature T_G and the thermal resistance R_{th}, th the power-factor error must be expressed, not in terms of percentage, but in

terms of a constant. For example, a power factor of 0.05 is known to be correct within the limits $\pm$ 0.005 and not $\pm$ 10 per cent.

The relation of the power factor error $\Delta \cos \theta$, and E^2/G_2 is shown in Fig. 1 for various values of ΔT_G. When the power-factor error has been calculated for an equivalent temperature error of 1 deg. cent. ($\Delta T_G = 1$), it is very easily obtained for other temperature errors. The power-factor error increases in the same proportion as the temperature error. For example, if $\Delta \cos \theta = 0.0331$ when $\Delta T_G = 1$, then $\Delta \cos \theta = 0.0662$ when $\Delta T_G = 2$.

The curves in Fig. 1 show that the required accuracy of power factor measurements increases as the value of E^2/G_2 increases. For the sake of illustration, an equivalent error of 3 deg. cent. may be assumed in the base temperature. Under this condition the power factor of cable No. 9 should be measured with an error not to exceed 0.008. On the other hand, cable No. 2 may have a power-factor error not greater than 0.07.

A conversion of the term ΔT_G into its corresponding effect on the current carrying capacity of the cable may be helpful. The following formula provides the solution:

$$\frac{I_e}{I} = \sqrt{\frac{\cos \theta_0 - \cos \theta - \Delta \cos \theta}{\cos \theta_0 - \cos \theta}} \qquad (6)$$

I_e is the current capacity of the cable when its power factor is $(\cos \theta + \Delta \cos \theta)$.

I is the current capacity of the cable when its power factor is $\cos \theta$.

Fig. 1 supplies values of $\Delta \cos \theta$ for various cables and for various values of ΔT_G. Table I contains values

*The column of Cos θ_0 is, on first consideration, more ridiculous than interesting. Some of the values are imaginary. This column of figures gives the power factor which each cable would have if it had zero current carrying capacity. Those cables for which the figure is greater than unity will carry current regardless how great the basic power factor cos θ may be (cos θ, of course, will never be greater than unity). On the other hand, when the figure becomes rather low, as for example Cable No. 9, it has a significant meaning. This cable will not carry current at 60 deg. cent, if its power factor is equal to 0.113 at 60 deg. cent.

of $\cos \theta_0$ and $\cos \theta$. Fig. 2 shows the effect of different values of ΔT_G upon the current capacity of the ten cables listed in Table I, when N equals six and when the basic power factor is that listed in the Table.

When N Equals Any Number

The subject thus far has been confined to the condition of six similar cables in a duct bank. The question naturally arises as to how the desired power-factor accuracy would change if some other number of similar cables in a duct bank were chosen. The change can easily be shown by introducing a factor Q.

$$\Delta \cos \theta = Q \, \Delta \cos \theta \, (N = 6) \qquad (7)$$

$$Q = \frac{R_{th} \, (N = 6)}{R_{th}} \qquad (8)$$

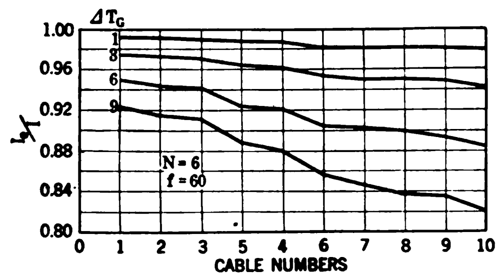

Fig. 2—The Effect of a Change in the Base Temperature Upon Current Capacity of Three-Conductor Paper-Insulated Cables

By trial calculation on the ten cables listed in Table I, Q was found to be constant, within an average deviation of 1.3 per cent. The following values of Q can be safely used for the purpose of this paper:

N =	2	4	6	8	10	12
Q =	1.85	1.30	1	0.81	0.69	0.59

The use of Q can easily be seen by referring to Fig. 1. The values of $\Delta \cos \theta$ for a condition of $N = 4$, may be obtained upon multiplying the values taken from Fig. 1 by 1.30. Likewise, the values of $\Delta \cos \theta$ for a condition of $N = 12$, may be obtained upon multiplying by 0.59. Because Q becomes smaller as N increases, the conclusion follows that power-factor measurements should be obtained with greater accuracy as the number of similar cables in a duct bank increases.

According to formula (6), the power-factor error $\cos \theta$ should become less as $\cos \theta$ increases in order that the ratio I_e/I may remain constant. If the limits of

the power-factor error should be based on the condition that the error must not affect the current capacity of a cable by more than a certain percentage, then evidently, the accuracy of power-factor measurements should increase as the value of the power factor increases. This reasoning is not valid. Even though a cable of high power factor should be measured with a higher degree of accuracy, nothing would be gained in current capacity because the equivalent error ΔT_G would not permit a gain. The conclusion, therefore, follows that the required power-factor accuracy cannot be based directly on a limited change in current capacity.

Single-Conductor Cables

A slight modification of Simons' equation (**26**) for current capacity yields formula (**9**):

$$I = \frac{31.6}{\sqrt{R \dfrac{R_{ac}}{R_{dc}}}} \sqrt{\frac{T_0 - T_G - R_{th'} W_{DL}}{R_{th}}} \qquad (9)$$

The ratio $\dfrac{R_{ac}}{R_{dc}}$ is introduced because the skin effect in large conductors becomes appreciable. The term $R_{th'}$ is somewhat different from R_{th} because in the case of single-conductor cables the dielectric power loss is not assumed to originate on the surface of the conductors but actually originates in such a location as to cause a temperature drop from conductor to sheath equal to one half the drop it would have if the dielectric power loss had originated on the surface of the conductor. The value of R_{th} must be calculated in such a manner as to take into account sheath losses which are of relatively large magnitude in single-conductor but negligible in three-conductor cables. The other terms in formula (**9**) are the same as those in formula (**1**).

The ratio of R_{ac}/R_{dc} is taken from Simons' paper[3], p. 369. R_{th} and $R_{th'}$ were calculated according to his method. However, 500 watts per cm. units were used, in place of his 850 watts per cm. units, as the heat resistivity of impregnated paper.

By introducing the terms ΔW_{DL} and ΔT_G in formula (**9**), the following formula is obtained:

$$\Delta W_{DL} = \frac{\Delta T_G}{R_{th'}} \qquad (10)$$

3. *Loc. Cit.*

Stating ΔW_{DL} in terms of $\Delta \cos \theta$ and $\dfrac{e^2}{G}$ formula (**10**) becomes:

$$\Delta \cos \theta = \frac{46.5}{e^2/G} \frac{\Delta T_G}{R_{th'}} \qquad (11)$$

e = voltage to neutral in kilovolts. In single-conductor cable it is the voltage from conductor to sheath.

G = Geometric factor

k = 3.4 and f = 60.

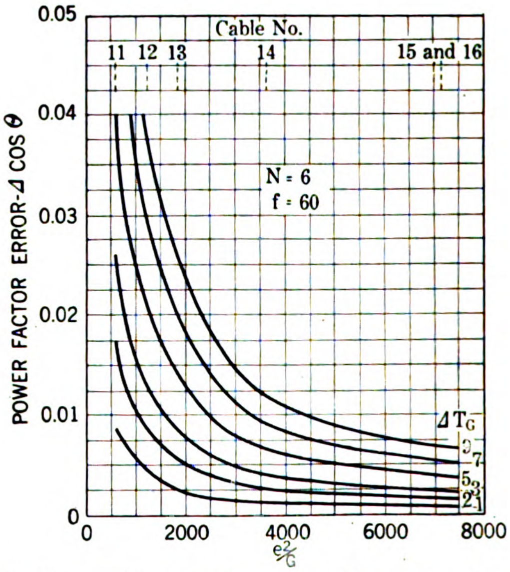

FIG. 3—POWER FACTOR ERROR IN TERMS OF EQUIVALENT BASE TEMPERATURE ERROR ΔT_G FOR VARIOUS SINGLE-CONDUCTOR PAPER-INSULATED CABLES

The power-factor error $\Delta \cos \theta$, is given in Table II when $\Delta T_G = 1$, for six different cables when N equals 6. The center of each of the three cables on a three-phase circuit was assumed to be at the apex of an equilateral triangle, the sides of which were taken to be 12 in. long (S = 12). Cables No. 14, No. 15 and No. 16 each has a hollow core of ¾ in. diameter in the conductor. All the cables are assumed to have a single lead sheath the thickness of which is given as U in 64ths of an inch. The thickness of the insulation in 64ths of an inch is given as T.

In Fig. 3 the relation of power-factor error, $\Delta \cos \theta$, to the ratio e^2/G is shown for various values of ΔT_G.

As in three-conductor cables, the power-factor error is easily obtained for other values of ΔT_G when it is known for one value of ΔT_G. If $\Delta \cos \theta$ equals 0.005 when ΔT_G equals unity, then $\Delta \cos \theta$ equals 0.01 when ΔT_G equals 2. The curves show that for high-voltage single-conductor cables, the permissible power-factor error is much less than it was for the three-conductor cables considered in Fig. 1. If the equivalent error

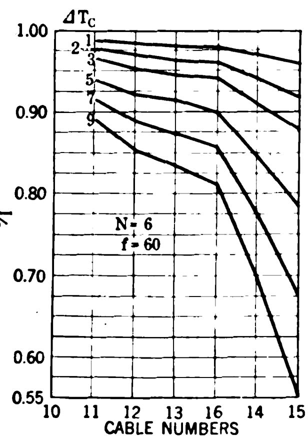

FIG. 4—THE EFFECT OF A CHANGE IN THE BASE TEMPERATURE UPON CURRENT CAPACITY OF SINGLE-CONDUCTOR PAPER-INSULATED CABLES

ΔT_G, in the base temperature is assumed to be 3 deg. cent., then the power-factor error, $\Delta \cos \theta$, should not exceed 0.0022. This accuracy would be required regardless of what the actual power factor of the cable may be.

The frequency used in the calculations is 60 cycles. If some other frequency were used, the permissible power-factor error would change. Although the exact variation of dielectric power loss with frequency is not known, the dielectric power loss may be considered to be proportional to the frequency within the limits of commercial power frequencies. On this basis, the permissible power-factor error, both for single-conductor and three-conductor cables, varies inversely as the frequency. In other words, the greater the frequency, the greater should be the power-factor accuracy.

The effect of ΔT_G upon the current capacity of single-conductor cables can be calculated by formula (**6**). This effect is shown in Fig. 4, when N equals 6 and when the basic power factor is that given in Table II.

If N equals some other number, the power-factor error $\Delta \cos \theta$ may be obtained by formula (**7**). In this case

$$Q = \frac{R_{th'} (N = 6)}{R_{th'}} \qquad (12)$$

The values of Q may be considered as follows:

$N = 3 \quad 6 \quad 9$

$Q = 1.50 \quad 1 \quad 0.75$

132-Kv. Cable

Fig. 4 brings out some rather interesting information. Each curve has a sudden break at cable No. 16, consequently, cables No. 14 and No. 15 have some property which is abnormal relative to the other cables. This property is the power factor $\cos \theta$. Even though cable No. 15 has a power factor which is only 0.02 at 60 deg. cent., this power factor value is relatively much higher than the power factor 0.029 at 60 deg. cent. is for cable No. 12. Cable No. 15 should have a power factor of the order of 0.01 at 60 deg. cent. in order that that cable may perform in accordance with experience with other cables. The equivalent base temperature error ΔT_G, should be low and also the power-factor error $\Delta \cos \theta$. Furthermore, the power factor of the cable and the heat resistance of the cable and the duct line must run very uniform throughout its entire length for satisfactory and economical service.

Fig. 5 shows the power factor—temperature characteristic $A B$—which cable No. 15 may be expected to have, and characteristic $C D$ for Cable No. 16. Each

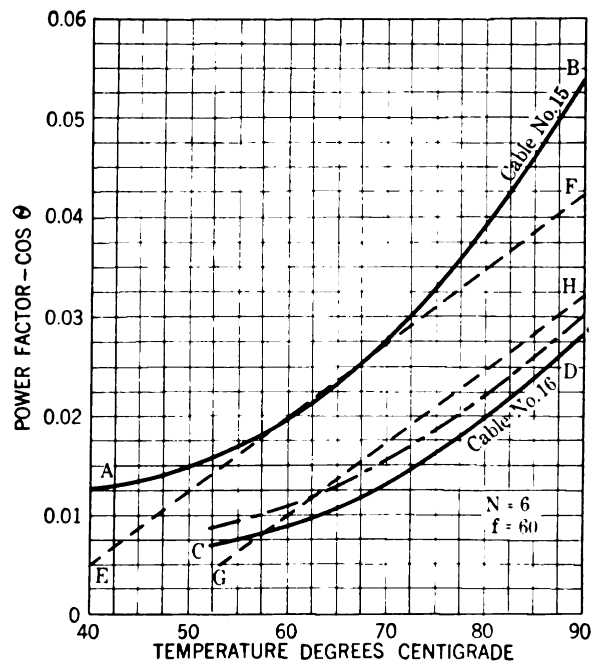

FIG. 5—CABLE NO. 15 WILL HAVE A SHORT LIFE REGARDLESS OF POWER FACTOR ERRORS. AN ERROR OF 0.002 MAY JEOPARDIZE THE LIFE OF CABLE NO. 16

132-kv. cable
One-conductor, 600,000 cir mils
3/4-in. hollow core
46/64-in. insulation

of these characteristics was obtained in actual power-factor measurements of finished cables. The dotted line $E F$ is the unstable power factor—temperature characteristic for Cable No. 15 and likewise the dotted line $G H$ is the unstable characteristic for Cable No. 16.

The current capacity of Cable No. 15 is calculated to be 187 amperes when it is operated with a conductor temperature of 60 deg. cent. and a power factor of 0.020 when N equals 6. If this cable had $E F$ in Fig. 5,

as its power-factor characteristic, it would carry 187 amperes at any temperature from 40 to 90 deg. cent. or more. Nobody knows what temperature the cable would choose.

The unstable characteristic $E\,F$ is obtained with the use of formula (**11**). Instead of using $\Delta \cos \theta$ as a power-factor error, it is used as a power-factor increment. For the term ΔT_G, ΔT_0 is used because an increment change in T_0 produces the same effect as an increment change in T_G according to formula (**9**). Formula (**11**) then becomes:

$$\frac{\Delta \cos \theta}{\Delta T_0} = \frac{46.5}{e^2/G} \frac{1}{R_{th'}} \qquad (\mathbf{13})$$

Formula (**13**) provides the slope of the characteristic $E\,F$. The point, $\cos \theta = 0.02$ and $T_0 = 60$, on the characteristic is already known. The characteristic is, therefore, established by a point and the slope. In the derivation of the slope the change in the resistance R due to an increase in temperature is disregarded. The actual power-factor characteristic of Cable No. 15 is the curve $A\,B$. With a current of 187 amperes flowing in this cable, its temperature will rise to 60 deg. cent. Now, if the current should increase slightly to 190 amperes, the cable temperature would immediately rise indefinitely. Even if the current should drop back to 187 amperes when the temperature has reached 70 deg. cent., the temperature would continue to rise anyway because the cable temperature has passed the critical point of 68 deg. cent. This temperature is generally known as the critical temperature of cumulative heating. Cable No. 15 is not suited for 187 amperes, because a small error in the thermal data or power factor of the cable would cause cumulative heating.

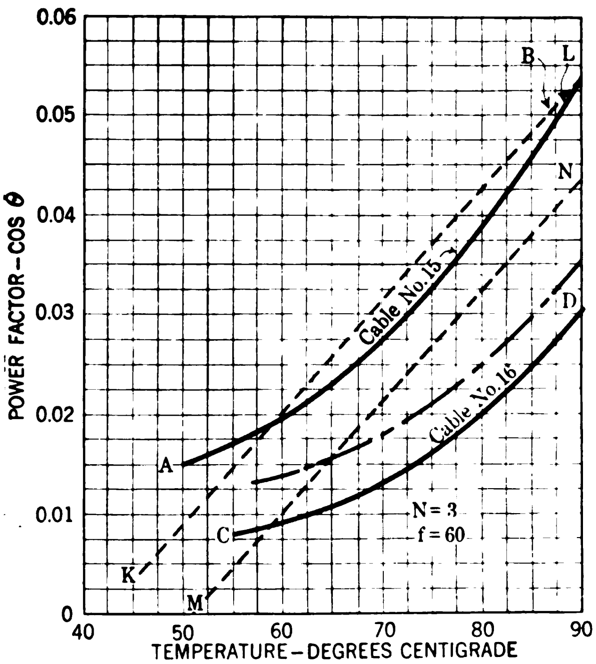

Fig. 6—Elimination of Power Factor Error and Equivalent Base Temperature Error Might Save Cable No. 15. An Equivalent Power-Factor Error of 0.005 May Not Seriously Impair the Use of Cable No. 16

132-kv. cable
One-conductor, 600,000 cir. mils
3/4-in. hollow core
46/64-in. insulation

The current capacity of Cable No. 16 is calculated to be 268 amperes at 60 deg. cent. with a power factor of 0.01 when N equals 6. With a current of 268 amperes flowing through it, this cable with its power-factor characteristic $C\,D$, in Fig. 5, would come up to a temperature of 58 deg. cent. provided no power-factor error exists and that all other cable and duct properties are known exactly. If, however, a power-factor error of 0.002 or an equivalent base temperature error of 3 deg. cent. exists, the cable would come up to a temperature of 63 deg. cent. and stay there as long as nothing changes. A little overload for a few hours might, however, seriously jeopardize the life of the cable.

Fig. 6 tells a similar story except that N equals three. The current capacity of each cable at 60 deg. cent. is calculated to be 303 amperes for Cable No. 15 and 358 amperes for Cable No. 16. The power factors are 0.020 and 0.010 respectively. Cable No. 15 does not offer a continuity of service of 303 amperes because a small error in the power-factor measurement or in the equivalent base temperature might send the temperature up to the point of cumulative heating at 90 deg. cent. Cable No. 16 looks promising for 358 amperes even though a power-factor error of 0.002 might exist. If in addition to a power-factor error of 0.002, an equivalent base temperature error of 4 deg. cent. exists the probable error of the combination would be of the order of 0.005. Even with this equivalent error of 0.005 in the power factor, the cable would probably continue to serve with 358 amperes but no overload should be permitted. Under this condition it would operate at 65 deg. cent.

For the 132-kv. cable, for operation in a three-cable duct bank, the power-factor error evidently should not exceed 0.002 and the equivalent error in the base temperature should not exceed four deg. cent. in order to obtain a cable service similar to that obtained with cables of lower operating voltage.

Conclusions

A survey of the factors which have a bearing upon the accuracy required in power-factor measurements shows that:

1. Power-factor accuracy should be stated as a constant and not as a percentage. For example, a power factor of 0.05 is accurate within $\pm$ 0.005 and not $\pm$ 10 per cent.

2. The power-factor accuracy required increases in direct proportion to the frequency, and also to the specific inductive capacity of the insulation.

3. The power-factor accuracy required increases as

the number of similar cables in a duct bank increases.

4. The required accuracy increases as the ratio E^2/G increases, where E is the operating voltage, in kv. and G is the geometric factor of the cable.

5. The required power-factor accuracy cannot be defined by percentage limits in the current-carrying capacity of a cable.

6. The required accuracy is relative to the accuracy obtained in the measurement of the heat resistivity of the insulation, the surface heat resistivity of the lead sheath, the "heating constant" of the cable duct and the base temperature of the earth.

7. For 132-kv. cable the power-factor accuracy should be of the order 0.002.

Electrochemistry and Electrometallurgy

Annual Report of the Committee on Electrochemistry and Electrometallurgy*

G. W. VINAL, Chairman

To the Board of Directors:

The Committee on Electrochemistry and Electrometallurgy of the Institute makes its annual report dealing primarily with a review of some of the outstanding developments within the field of the Committee's work. At the beginning of the administrative year the Committee was enlarged to include members representing as far as possible the many diverse fields that are included within the scope of electrochemistry and electrometallurgy.

The Committee has endeavored to bring about a closer cooperation between its own work and that of the American Electrochemical Society with which it should be closely identified. The work of our Committee does not overlap that of the Electrochemical Society, and it is apparent that a still greater degree of cooperation between the two organizations would be valuable[1].

In 1925 Mr. F. E. Smith, President of the London Physical Society, advocated the replacement of the present international electrical units by the absolute cm. g. sec. units. This is not a new idea, but it is an indication that we are approaching a time when such a step may be considered possible. The accuracy of the electrical standards must keep ahead of the demands of engineering. Improved facilities and technique for performing experiments within the physical laboratory are making possible a step which is of particular interest within the field of electrochemistry where the transformation of energy in its various forms plays an important part.

The international electrical units upon which the fundamental measurements of electrical engineering are based are defined by standards which are essentially electrochemical. The mercury ohm which serves as the standard for the measurement of resistance involves chemical and electrochemical processes for purifying the materials. The silver voltameter, whose electrolytic deposits serve to define the ampere, is obviously an electrochemical device. The standard cell, whose voltage has been determined by experiment from the international ohm and the international ampere, is essentially a small voltaic cell. Engineers become so accustomed to dealing with volts and amperes and ohms that the fundamental standards for their values are taken more or less as a matter of course. These fundamental standards were re-defined by the International Conference on Electrical Units and Standards which met in London in 1908. They were devised to represent as nearly as possible the absolute units based upon the centimeter, the gram, and the second. It is highly desirable for reasons that are too obvious to require repetition that they should represent these absolute units as closely as possible. With the increasing facilities for experimental work and improved technique, it is now possible to realize by experiment the absolute values of the fundamental units with a higher degree of accuracy than had been obtained prior to 1908. Experimental work is now in progress in the United States to verify the conclusions of experimenters at the national laboratories of England and Germany within the past few years, which have indicated that the mercury ohm does not represent the absolute ohm with as high a degree of accuracy as was previously supposed to be the case. Fifteen years have elapsed since the international experiments using the silver voltameter were made. During that time our electrical units have been carried forward by means of the working standards of the laboratory, that is to say, the wire-resistance standards and the standard cells. Developments in engineering practise are making it more than ever important that the fundamental elec-

1. The committee is indebted to Dr. Fink, Secretary of the American Electrochemical Society, for furnishing certain information used in this report.

Presented at the Annual Convention of the A. I. E. E., White Sulphur Springs, W. Va. June 21-25, 1926.

trical standards, maintained with the highest possible degree of accuracy, should be in accord with our cm. g. sec. system of measurements. Therefore, a difference between the value of the international ohm and the absolute ohm amounting to five parts in 10,000, together with its effect upon the value for the standard cell must inevitably give rise to serious consideration.

An outstanding development in electrodeposition during the past year has been made in chromium plating. Although it has long been known that chromium could be electrodeposited, it is only within the past few years that the conditions for its commercial deposition have been defined. There are still many problems requiring study before its general application will be entirely feasible. There are at least twenty laboratories in the country now engaged in the study of chromium plating, and while it is not yet in extensive use, the indications are that it will soon find many important industrial applications. Chromium is a material of extreme hardness and is also notable for its resistance to tarnish and to chemical action. It has been successfully applied to plates used for printing paper currency at the Bureau of Engraving and Printing, and it has materially increased the useful life of these plates. It will probably find application also in other forms of printing where very great numbers of copies are required. It has been suggested also for use on dies and gages. Although the reflecting power of chromium is appreciably less than that of silver, its resistance to tarnish may make it of decided value on reflectors.

In an effort to prevent corrosion, research has been in progress to improve the quality of nickel plating and eliminate the pits and pores which have been the chief cause of its failure to prevent the corrosion of underlying iron or steel.

A process recently developed and known as "galvannealing," is said to be an improvement over the familiar processes of galvanizing. It is claimed that the zinc covering is more uniform and flexible.

The protection of iron by cadmium would not be anticipated from the potential relations of these metals as usually given. Experiments, as well as actual service, indicate that cadmium can be used successfully as a protective material against corrosion of iron and steel.

Chromium plating, while not affording an absolute protection against corrosion unless the deposits are unusually thick, may be used in combination with underlying coats of copper and nickle, to afford a high degree of protection. Efforts have also been made to develop electroplating of simultaneous deposits of copper and nickle similar to monel metal. The importance of corrosion research to industry in general is very great and will doubtless assume even greater importance.

The progress of electrothermics during the past few years has been so rapid that publications of even recent date often must be used with caution lest they be misleading as to present practise in melting and heat-treating furnaces. During the past year, the development in the use of electricity for heating and industrial purposes has been rapid, but the idea sometimes expressed that all industrial heating processes are potentially valuable outlets for electrical energy has been considerably modified. In general, engineers are beginning to realize that, while there are many processes which can be done electrically, there is, nevertheless, a choice to be made which depends upon practical and economical aspects of fuel costs and the present state of manufacturing processes.

Soaking pits, electrically heated by resistors, have been found to yield ingots that can be more easily and economically rolled in certain plants than similar ingots from gas-fired pits.

Results obtained by the use of electric furnaces in the production of steel, ferro-alloys, and other operations of a similar nature depend very largely on the control of the electrical energy applied to the furnace. The electric furnace is not an inherently efficient piece of apparatus unless the electric energy is properly applied. This means that furnaces should operate in such a manner that the power is fully utilized with respect to time factor, load factor, and, when alternating current is employed, power factor. Aside from the more obvious advantages of high power factor, some electrochemical operations may be adversely affected by variations in power factor for reasons that are not at once obvious. Current density often plays an important part in metallurgical operations and when the control of the furnace is accomplished by means of current regulators, material variations of power input may occur. Thus, in operating a three-phase furnace, the variations in power factor during the melting-down period may keep the load in a state of unbalance with respect to the phases. It is sometimes observed that one electrode heats up unduly without, however, doing its share of the work. The electrical energy supplied is the important factor from a thermodynamic standpoint in metallurgical operations where a transformation of one kind of energy to another occurs. For both economic and metallurgical reasons, the control of the energy input is of important consideration. Modifications to meet practical conditions have been made in certain plants. Current control has been replaced by watt control, and individual motors for shifting the electrodes have been replaced by a hydraulic system which offers advantages in the accuracy with which an electric balance can be maintained during the period of melting. Some furnaces are now operating on 98 per cent of the energy supplied to the primary of the transformer, the two per cent loss being divided between the transformer, bus-structure, and electrode holders. The unequal power requirements during the various periods of charging, melting, refining, and tapping of steel furnaces have in some cases been

nearly equalized by staggering the operation of a group of three furnaces, having one transformer unit and one control mechanism. A more continuous load is thus maintained and the labor somewhat diminished, as measured by the weight of steel produced per man.

Because of the various states of oxidation of the metallic constituents of the ferro-alloys and the losses encountered in the reduction of them, some modifications in the usual method of charging the furnaces have been proposed. By very rapidly raising the oxides and reducing agents to the reducing temperature, the formation of intermediate oxide states is avoided. This is applicable to many types of reduction and is accomplished by a continuous charging of the material in a small stream into the hottest part of the furnace.

Up to a few years ago, the common practise in brass-rolling mills was to melt brass in crucibles, using coal or oil for heating. These crucibles generally held 600 lb., and some held as high as 900 lb of metal.

In the period from 1917 to 1922, the introduction and development of the induction type furnace, particularly in the Naugatuck Valley, met with considerable success, as it gave a better control of temperature for pouring, the metal was better (less contamination from gases, etc.), the metal losses were lower, and the cost of furnace linings was less than the equivalent cost of crucibles. These induction furnaces are rated 60 to 75 kw., single-phase, 25 or 60 cycles, and 220, 440, or 550 volts, and can melt 600 to 900 lb. of heat. Pouring temperatures needed for the general run of production requirements are within the working limits of the lining material used in these furnaces. For certain metals, such as nickel, silver, high copper alloys, etc., higher pouring temperatures are necessary, and difficulty has been experienced with the present lining materials.

Because of this situation, experiments have been carried on with a high-frequency induction furnace, and as a result, twelve of the furnaces have just been put into commercial operation in Waterbury. It is interesting to note that the first experiments with high-frequency furnaces were based on the use of 12,000 cycles; standard type generators were not available for this frequency, and mercury-arc oscillators were used, but these were limited in regard to power output. The experiments referred to above showed that much lower frequencies could be used. The high-frequency furnaces are rated to 100-kw. capacity, single-phase, 480 cycles, 1850 volts. For the twelve furnaces, two special frequency-changer sets, each rated 600 kw., are used. Because of the low power factor at which the furnace operates (10 to 12 per cent), a bank of capacitors, rated approximately 950 kv-a., is used with each furnace. The resultant power factor as measured at the frequency-changer set, is close to unity.

The construction of the furnace is relatively simple; it consists of a crucible which holds 600 lb. of metal, surrounded by an edge-wound copper coil, together with a blower, this assembly in turn arranged in a frame in such a way as to permit of tilting and pouring the metal. These furnaces have been in successful operation since the first of the year and additional furnaces are now being installed elsewhere.

An electric furnace for tempering steel parts and employing a forced convection, for obtaining uniform temperature conditions throughout the furnace, has been described recently. Experimental work is again in progress on a zinc furnace which embodies an electrothermic distillation process.

Other uses for electricity in electrometallurgy that have been noted recently include the electric heating of ingots after casting to keep the metal fluid and prevent piping. Heating for this purpose takes the form of an arc playing on the top of the ingot.

Also there has been an increasing use of electricity for annealing purposes, and it is significant that the range of objects which are subjected to an electric annealing process is steadily increasing. Annealing of the non-ferrous metals without oxidation has now become possible. Development of the mechanical operation of furnaces for enameling, to provide a continuous cycle of operation, is desirable.

Efforts are being made to improve the life of resistor products, and developments in the design of some furnaces to permit making repairs without the necessity of cooling the furnace are significant of possible development of continuous operation.

In discussing electrical power for chemical plants, it has recently been pointed out that these are not all dependent upon cheap power such as might be obtained from a hydroelectric development. Many of those which are not thus dependent produce, or could produce, cheap power for their own motor drives as a by-product of process steam. Chemical plants may be differentiated into those which require large quantities of cheap power and those which require large quantities of steam. The former include electrochemical and electrometallurgical plants for electrolytic processes and furnace work, while the latter class include those which require heating at lower temperatures, such as may be obtained from steam. The tendency at the present time in relation to the use of power by chemical plants has been summarized in the following paragraphs.

Where considerable steam is required for heating and process work, the chemical plant should generate its own steam at high boiler pressure and then obtain electrical power for its mechanical drives and electrolytic circuits from that steam before turning it over as exhaust or bled steam to the processes.

Very highly efficient turbo-generator units of medium size are now available.

Where the boiler and prime mover rooms are in close proximity to the electrolytic cell or tank room, the electrolytic power should be generated as d-c. power

Very highly efficient geared d-c. turbo-generating units are now available.

Where appreciable distance intervenes between the boiler and prime mover rooms and the tank house or cell room, or where appreciable steam is not required for heating and process work, so that the electrical power is purchased, then, in the great majority of cases, the best economy will be obtained by converting the electrolytic power from alternating current by means of synchronous converters.

The inefficiency of the motor-generator set as a means of conversion from alternating current to direct current as compared to the transformer synchronous converter unit, is all the more apparent when the operating conditions of the plant drop below full-load conditions.

The power factor of an electrochemical or electrometallurgical plant is relatively high, owing to the large proportion the electrolytic load at unity power factor bears to the total motor load. It is, therefore, seldom necessary to provide power factor corrective means within such plants to bring the overall power factor within the usual commercial range.

One of the arguments advanced by those who urge use of cheap hydroelectric power for electrochemical and electrofurnace processes is that these industrial operations afford very high annual capacity load factor. They are, therefore, a type of user who justifies the relatively high investment per unit of electrical capacity that is necessary with hydro plants.

Several papers of interest to electrical engineers were presented at the Chattanooga meeting of the American Electrochemical Society. The feature of the meeting was a symposium on the relation of the electrochemical industry to the production of fertilizers. Recent developments in nitrogen fixation are significant to the engineer, because the power requirements are changing as a result of the work of the chemist. Synthetic ammonia, which is one of the forms of fixed nitrogen, is not supplying a product for fertilizer purposes as may be generally supposed, but rather is displacing ammonia from other sources for refrigeration and chemical use. The arc process for the fixation of nitrogen has found very little use in this country, but research on the atomic states and modes of energy transfer suggest possible new developments in this line. Concentrated fertilizer materials including ammonia, urea, nitric acid, phosphoric acid, and their compounds, were discussed. The power supply and economics of the situation are only a part of the nitrogen problem. Other factors that vitally affect the electrochemical side of this industry are the physical characteristics of the materials produced, their suitability for a variety of crops, transportation charges, and, not least, the reaction of the farmer himself.

The electrical properties of the copper-nickel-manganese series of alloys have recently been investigated with reference to resistivity, the temperature coefficient, and the thermoelectric power against copper and mechanical properties. A paper describing this work was presented before a recent meeting of the Electrochemical Society. It seems possible that resistance alloys superior to those now in common use may become available. This is important to the electrical engineer, particularly in connection with instruments. which may be subjected to wide variations in temperature

The development of radio has stimulated the production of batteries, including both dry batteries and storage batteries. A new form of caustic-soda battery which requires only the addition of water has also appeared. The battery industry has watched with some concern the increasing efforts to provide battery eliminators for radio sets, but as yet it seems probable that little of inroads on the battery industry has been made. Coincident with this, there has been a marked improvement in the performance of certain types of small rectifiers. The life of the aluminum rectifier has been greatly increased and it is now used as one form of battery eliminator, and, together with several storage cells, makes possible the operation of radio sets from a-c. power. Also other types of small rectifiers for trickle charging of storage batteries have been developed.

Chlorine, which is a product of the electrochemical industry, was discussed at length in a symposium on the subject held by the Electrochemical Society at its recent meeting in Chicago. Papers included the economics of chlorine production, discussion of transportation problems, the chemistry of bleaching powder, and other uses for it.

A UNICONTROL HIGH-FREQUENCY RADIO DIRECTION FINDER

The Bureau of Standards was asked to develop for the United States Coast Guard, a simple type of radio direction finder which should function on 2100 kc. (143 m). Such a device enables a ship so equipped to locate another ship readily. A paper under the above title, by F. W. Dunmore, (Scientific Paper No. 525 of the Bureau of Standards) describes the development of such a direction finder and its installation on a Coast Guard patrol boat. The direction-finder coil consists of four turns of ignition cable, wound on a 20-in. frame. It is installed over the pilot house and rotated from below. A tuning unit and coupling transformer have been designed so that the direction-finder coil may be used on the ship's receiving set without changing its tuning adjustments, which are locked in the 2100-kc. position. A special form of automatic balancing condenser, operated by a special cam rotating with the direction-finder shaft, is incorporated in this instrument. Thus a clear minimum may be obtained at all angular positions of the coil without manual operation of the balancing condenser. The controls necessary when taking a bearing are in this manner reduced to one—that of rotating the direction-finder coil to obtain the minimum signal.

Some Aspects of the Dielectric Loss Measurement Problem

BY B. W. ST. CLAIR[1]
Member, A. I. E. E.

***Synopsis.**—This paper points out some of the difficulties of making accurate power measurements at very low power factors. It deals with the lack of reference standards of known and constant power factor, especially for moderate sized samples and at high voltages. It also points out that a method of measuring an added loss as a check on a given test outfit's accuracy is not a check at all, although it has been used as such in several instances. Reference is made to calorimetrical methods of calibrating a testing outfit and to special forms of resistors that have very low time constant and are suitable for this class of test work.*

POWER measurements at very low power factors are admittedly quite difficult. The literature of the subject is quite voluminous, and many schemes, most of them modifications of two or three fundamental ones, have been proposed and used by various observers. It is not unusual to get widely varying results when a given sample is tested by different methods in different laboratories. Unfortunately, the real difficulties of this kind of measurement are not so widely appreciated by general testing engineers as perhaps they should be. It is the function of this short paper to point out some of these difficulties. No attempt is made however to have it cover the complete field of dielectric measurements.

A most difficult feature of this general problem centers around the lack of a reference standard of known loss. For work on very small samples, and at relatively high frequencies, this statement might be challenged. For power frequencies and for apparatus such as cables and condensers, there is no suitable reference standard, especially when consideration is given to the relatively high voltages under which tests must be made. Without an adequate reference standard, there can be no definite assurance that the results obtained by a given test set are correct, except as inference can be drawn from various auxiliary tests on the equipment or on the apparatus in test.

An air condenser, or an air condenser plus a known series resistance, has been repeatedly suggested as a suitable standard. There are two real difficulties in this suggestion. One is the difficulty of building an air condenser of adequate size and voltage rating, and the other is in knowing the losses of the condenser or proving the lack of losses at the high voltage necessary for tests on finished apparatus. Air condensers of small size and for low-voltage ratings have been built, but they do not lend themselves to either bridge methods or wattmeter methods on many of our present-day engineering samples. A number of air condensers designed for low loss at moderately high voltages has been built and are in service. Their capacitance, however, is quite low, especially when compared to reel lengths of cable or to condensers for power-factor correction. It is possible to build up a bridge with an air condenser as one of the arms, but the results of the bridge tests are still uncertain because of the very large ratio of the resistance arms necessary if the test work is on sizable samples and at the more usual voltages; and also there is no ready means of checking the results of distributed capacity and capacity between various high-voltage parts of the bridge and ground. A complete demonstration of the dependableness of a bridge scheme might lie in the interchangeability of the standard air condenser and the test sample. At present this is almost hopelessly impossible, at least with samples of moderate size.

Air condensers at present are also inadequate as reference standards for wattmeter methods. If a wattmeter is checked against a known air condenser at low voltages, it cannot be used at high voltages with any real assurance that the calibration can be translated from the low-voltage values. The currents that would circulate in the windings of wattmeters from air condensers at low voltage would be very different from those from actual cable samples or from static condensers. A calibration by air condenser is then generally carried over to another winding of the dynamometer with no really definite way of proving that this change can be made without change of instrument constants or characteristics, or the calibration is carried over to a much higher voltage without assurance that no change has occurred.

Another line of attack has been to eliminate all the known causes of error and then to attempt to prove the over-all accuracy of the equipment by checking a sample and then checking the sample with a known loss added to it as a series resistance. If the results corrected for the known losses were about the same as the results on the sample alone, the assumption was made that the measuring outfit gave correct results.

There are several reasons why this is not a dependable check of the test apparatus. If large changes are made in the losses, so that the dielectric loss plus the added losses are large in comparison with the dielectric losses, the difference is obtained by subtracting two large quantities. With only ordinary precision in the measurement of these large quantities the difference is

1. General Electric Co., West Lynn, Mass.

Presented at the Regional Meeting of District No. 1 of the A. I. E. E., Niagara Falls, N. Y., May 26-28, 1926.

subject to large uncertainties. Unless the change is made very great there is no check possible because of certain peculiarities of the trigonometric functions over the range of angles with which this paper deals.

From zero to five deg. the sine and tangent are for this purpose identical and have a linear relationship to the angle, thus

$$\sin X = 0.0174\,X$$
$$\tan X = 0.0174\,X \qquad (1)$$

where

X is expressed in degrees.

Now 5 deg. corresponds to a power factor of 8.7 per cent which is larger than is usually met in dielectric work on finished apparatus at power frequencies. The usual range is from 0.1 per cent to one or two per cent. The phase angle mentioned here is the departure of the current from an exact quadrature position with its voltage. Thus, the power factor of the sample is represented by the sine of this angle. Because of the linear characteristics and identity of the tangent and sine functions the addition of resistance to the test sample results in a change of angle proportional to this resistance and also in a change of power factor proportional to this resistance.

If the sample had no loss the phase angle would be zero. If to this ideal capacitance should be added a series of resistance R, the phase angle of the combination of capacitance and resistance would be

$$\alpha = \tan^{-1} \omega\, C\, R \qquad (2)$$

where

$\omega = 2\,\pi$ frequency
C = capacitance of sample
R = added resistance

The power factor of this group is also $\omega\, C\, R$, thus

$$\text{power factor} = \sin \alpha = \tan \alpha = \omega\, C\, R$$

and the losses in this resistance are equal to

$$I^2 R = E\, I \sin \alpha \qquad (3)$$

The normal losses of a condenser or cable or other dielectric sample can be considered as due to a series resistance added to a pure capacitance. Thus one speaks of the equivalent series resistance of a given sample. Its magnitude is such that $I^2 R$ losses would equal the dielectric losses. This resistance is denoted by R_1, so that the phase angle of the sample is

$$\beta = \tan^{-1} \omega\, C\, R_1 \qquad (4)$$

where

R_1 is this equivalent resistance

and its power factor is

$$\sin \beta = \tan \beta = \omega\, C\, R_1$$

The addition of resistance R to a sample of equivalent resistance R_1 results in a change of phase angle just equal to what the phase angle would be if the sample had no loss, that is, if R_1 were zero. This can be easily shown:

$$\text{phase angle} = \tan^{-1} \omega\, C\,(R + R_1) \qquad (5)$$

Because of the linear characteristic of the tangent function this can be written as

$$\text{phase angle} = \tan^{-1}(\omega\, C\, R) + \tan^{-1}(\omega\, C\, R_1) \qquad (6)$$

The difference between this and equation (2) is

$\tan^{-1} \omega\, C\, R_1$ which is equation (4)

The wattmeter deflection when the sample is tested alone is

$$W = E\, I \sin(\beta + \gamma) \qquad (7)$$

E is applied voltage
I is current in the series circuit of the wattmeter
γ is the phase displacement of the armature current of the watt meter from its voltage. The difficulty of knowing the value of this angle is the chief difficulty in securing correct results in wattmeter methods at these low power factors. It is due to several things and may lag or lead its voltage. It is due to the inductance of the potential circuit resistance and of the armature of the wattmeters, to the capacitance currents flowing between various parts of the potential circuit and ground, and to eddy currents in the wattmeterstructure or windings. The general tendency is to reduce this angle to as near zero as possible by careful attention to the set-up of the test equipment. It remains, however, a more or less unknown quantity as the accurate determination of the inductance of the resistances is made only with difficulty and the capacity currents cannot be computed.

Equation (7) for the wattmeter deflection becomes

$$W = E\, I\,(\sin \beta + \sin \gamma)$$

(At the small angles which are to be considered, the cosine can be taken as unity.)

When the series resistance R is added to the circuit, the wattmeter deflection becomes

$$W_1 = E\, I \sin(\alpha + \beta + \gamma)$$

which reduces to (8)

$$W_1 = E\, I\,(\sin \alpha + \sin \beta + \sin \gamma)$$

The difference in the two deflections is

$$W_1 - W = E\, I \sin \alpha$$

which is just equivalent to the I^2R loss in the resistance R, Equation (3).

Throughout this discussion, I is supposedly unchanged by the addition of R. In practise this is true.

At first, if viewed on a non-mathematical basis, this result seems paradoxical. A wattmeter incorrectly measuring a circuit of unknown loss has a correct increment to its indications when a known loss is added to the circuit. If there were no loss (*i. e.*, no phase angle) in the sample and if the phase angle of the wattmeter potential circuit were zero, the wattmeter would indicate zero. Its indications are directly proportional to these angles. Any angle in either circuit causes a deflection (positive or negative) that is proportional to the angle. The wattmeter can then be thought of as an instrument with an unknown zero point and a linear scale. The addition of a known quantity to the circuits of an instrument of this type results in a correct increment of indication without affording a clue to the total quantity being measured

by the instrument. From the foregoing statements it is apparent that a wattmeter although indicating incorrectly will correctly show differences in two samples of the same capacitance. If the first sample is replaced by a second of identical capacitance the change in indication of the wattmeter is the difference in loss of the two samples, but no clue is given to the absolute magnitude of loss of either sample.

This discussion has been applied to wattmeters where the armature is allowed to deflect. A similar treatment with the same result applies to those cases where phase changing methods are used to reduce the wattmeter deflection to zero.

To reduce the unknown phase angle of the potential circuit to as low value as possible the general tendency is to use guarded circuits of some sort. There are three main points to consider in laying out the potential circuit of an equipment of this sort—inductance of the resistances, distributed capacity and capacity to earth and other parts of the circuit. Some forms of "non-

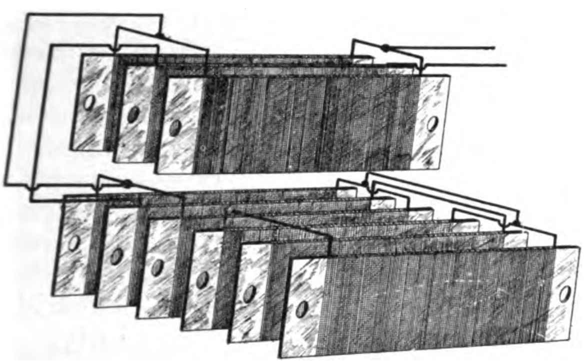

Fig. 1

inductive" windings have rather large distributed capacitance. Some also have residual inductances that though low are difficult to compute. It is also difficult to measure these residual inductances as the time constant must be very small. If the phase angle is not to exceed 1 min. at 60 cycles, the time constant must be less than 7.7×10^{-7} sec. At any event the phase angle should be known to at least 1 min. if the over-all accuracy of the outfit is to be good when working on equipment like condensers. The error 1 min. causes 14 per cent error in losses when working with samples having a power factor of 0.2 per cent and 3 per cent when working on samples of 1 per cent power factor.

A form of resistor that has low leakage, fairly low distributed capacitance, low inductance that is easily amenable to calculation, and is easily insulated for high voltage is the resistance card quite common in a-c. indicating instruments. A scheme of guard circuits that has proven very effective has been devised for this form of resistor. Every card is individually shielded as well as the case containing a group of cards. The general scheme is shown in Fig. 1 and the diagram of connections in Fig. 2.

In wattmeter methods either the potential losses or the $I^2 R$ loss in the series circuit of the wattmeter must be measured. In general, the series loss is by far the smaller of the two so that the scheme of connections shown in Fig. 3 is preferred to those of Fig. 4. If attempts are made to use very small samples, the inductance of these series windings may become excessive and must be allowed for in the computation of results.

The difficulties due to the absence of satisfactory no-loss standards of adequate size and voltage rating can be overcome in some cases where the test samples

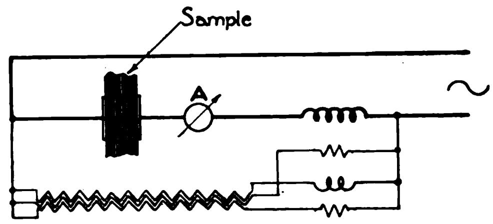

Fig. 2

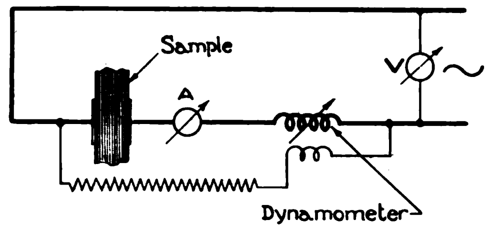

Fig. 3

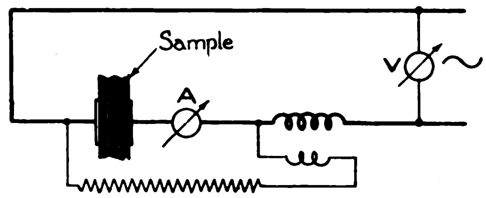

Fig. 4

are of appreciable size so that the losses are large enough to measure by calorimetrical methods.

While fairly satisfactory results are possible, the testing work must be of very high order and unusual care must be taken to prevent the acceptance of erroneous results. Several different calorimeter methods have been used or proposed. In some of them the volume and temperature rise of water flowing over the sample in a suitable case have been used. In others the temperature rise of various parts of identical casings, one of them with an actual sample and the other with a resistor of known value, have been used as reference accuracy standards for dielectric-loss measuring outfits. In another method, identical temperature gradients with dielectric losses as one heating element and a resistor on direct-current as the other have

been used to demonstrate the accuracy of a testing equipment. This method is somewhat more elaborate than the others, and in the hands of a careful experimenter and with sufficiently good temperature conditions and thermometers may yield very good results.

A photograph showing a test of this sort under way

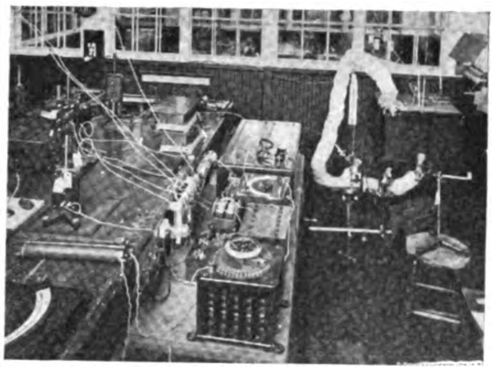

FIG. 5—CALORIMETER TESTS ON STATIC CONDENSER DIELECTRIC LOSSES

is shown in Fig. 5 and a diagram of the calorimeter is shown in Fig. 6.

The whole equipment was installed in a room the temperature variation of which throughout the calorimeter tests was not greater than 0.2 deg. cent. The temperature

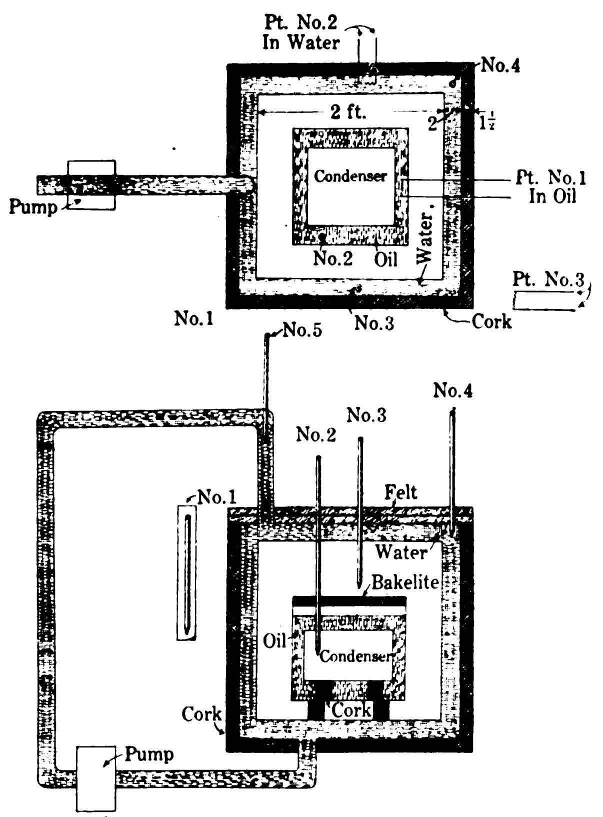

FIG. 6

rise of the water jacket and of the oil above the arbitrary reference temperature was determined to 0.002 deg. cent. This generally required six or eight hours. Immediately, thereafter the condenser was removed from circuit and resistances that had been built into the same case were connected to a d-c. circuit. The losses in these resistances were varied until the same temperature distribution was reached.

At this point it was assumed that the a-c. losses and the d-c. losses were the same. All readings were taken at a distance by telescope to prevent body radiation influencing the thermometers. Accurate speed control of the circulating pump was also in effect although the pump did not add appreciable heat to the water stream and the connections were very well lagged to prevent undue radiation into the constant temperature room.

Another source of disturbance is the change of wave shape of the current in the test sample. Because of the very low losses and the relatively large capacitance the tendency is to seriously accentuate any harmonics that may be present in the voltage wave.

The higher the harmonic the greater the amplification of that harmonic in the current wave. The phase position of the harmonic will also tend to advance beyond its normal position in the voltage wave and the

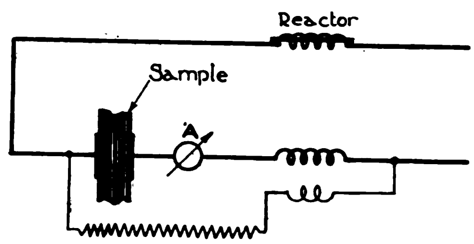

FIG. 7

losses due to the harmonics will in general be enhanced. This tends to reduce the leading tendency of the harmonic so that its phase shift is unknown. If the losses are measured correctly with appreciable wave distortion, the results are not those to be expected from sine wave currents of the fundamental frequency and measured voltage. This distortion of the wave also causes unknown error in the indications because of the unknown amplitude and phase position of these harmonics. A generally useful procedure that obviates this trouble is to obtain the required voltage rise by resonance or to use a reactance of very large value in series with the sample, if resonance is unadvisable. When the samples are small, resonance or a close approach to resonance is impossible or difficult at power frequencies. A circuit diagram is shown in Fig. 7.

In many checks of dielectric loss the shape of the power-factor curve with voltage is of more interest than is an exact knowledge of the actual loss. There is fortunately a fairly simple check that can be applied to a given wattmeter or bridge outfit to show its relative accuracy at varying voltages. This test consists in the selection of four samples of identical capacitance and apparent loss. These samples after check at a given voltage are connected in series multiple and tested at

twice the original voltage. This results in applying the original potential to each sample. The combined capacitance is equal to each of the original samples. Because of the identity of the samples and the application of the original test voltage, the power factor of the group should be the same as the original four samples, and the measured losses should be just four times the loss of any unit at the original voltage. Thus, with an outfit to work to 2500 volts, a comparison of the relative voltage errors of the 400- and 800-, the 600- and 1200-, the 800- and 1600-, the 1000- and 2000-, and 1200- and 2400-volt points might be made. If nine identical samples were available, a check of the 400- and 1200-, and the 800- and 2400-voltage errors might be made, using three series multiple groups and three times normal voltage.

Rural Electrification

BY G. C. NEFF[1]
Member, A. I. E. E.

Synopsis.—*This is a paper on rural electrification, discussing some of the problems connected with this important development. The paper points out the effect of power and machinery on the living conditions of the American farm and the part electricity may play. It discusses the things being done by the agricultural and electrical industries to direct and bring about a proper development of this service.*

According to a report of the United States Department of Agriculture, in the July 1925 issue of *Crops and Markets*, the total gross income of the United States farmers for the year ending June 30, 1925, was approximately twelve billion dollars. This figure includes the value of food and fuel products produced and consumed on these farms. A 1924 report of the Department of Agriculture shows that there are thirty billion man hours of human energy used annually on the farms of the United States and this figure does not include any time allowance for the work done by the women in the house. If the entire gross income of the farms of the United States of twelve billion dollars is used to pay for these thirty billion man hours the hourly wage would be 40 cents. From these earnings the farmers must support and provide for their families, must pay all of the operating expenses in connection with their farms, must pay taxes on property which has a value of approximately sixty billion dollars, and must provide interest on this huge amount of money which is tied up in farm lands and improvements thereon.

The above statement shows that if the farmers of the United States are to be put in a prosperous condition, the hourly wage per worker must be raised. This can be done by either increasing the income or by maintaining the present income with fewer workers. I believe that the latter can be accomplished through a proper and more liberal use of power and machinery. Due largely to wide distribution of electric power by public utility companies, and to the ease with which this power can be automatically controlled, it will play a big part in reducing the number of necessary workers and in increasing general farm prosperity.

A study of general conditions shows that a very close relationship exists between the income of each productive worker and the average amount of mechanical power available to the workers. In China, the mechanical power per worker is very low and the wages are also very low. The average amount of power available to the factory worker of the United States is higher than in any other country in the world and likewise the average wage is higher.

The same relationship holds true in different parts of our country. Again, the United States Agricultural Department Survey shows that the use of power per farm worker in certain southern states is much lower than in certain northern states, and the income per worker is much less in these southern states than in the northern states referred to above. It seems, therefore, that if the average income of the worker is to be raised, it must be through increased production per worker and this can only be done with the help of machinery and this calls for power. Therefore, proper electric power supply on the farm is something which may have much to do with farm prosperity itself.

While many farms are now and for some years will be supplied with electric service from the individual farm lighting units, general and permanent rural electrification will be brought about through a further expansion of our electric public utilities which now so efficiently serve our cities and villages. In fact, this expansion has begun and about four per cent of the United States farmers are now enjoying central station service. It might appear from this that practically nothing has been done by the utility companies in extending electric service to the farms. To correct this impression, please consider the following statements. In that part of the United States lying between the Alleghany Mountains on the east and the Rocky Mountains on the west are approximately 100,000 farms receiving central station service.

On the average, three farms can be served from one

1. Vice-President, Wisconsin River Power Co., Madison, Wis.

Presented at the Regional Meeting of District No. 5 of the A. I. E. E., Madison, Wis., May 6-7, 1926.

mile of rural line. Therefore, there are located in this middle section of the United States approximately 33,000 miles of rural lines. If these rural lines were put into long straight lines, they would extend from Chicago to Tokio on the west, to Constantinople on the east, to the southern tip of South America on the south, and to the North Pole on the north; and there would be enough line miles left over to build a line from New York to San Francisco and back again.

In the more thickly-settled region of the Atlantic Coast and in the region along the Pacific Coast, where electric service is used on farms for irrigation purposes, the number of farmers receiving electric service from central station lines is about equal to the number served in the great middle part of this country. The miles of line on the coast regions which are devoted to rural electric service add greatly to the mileage just described. This shows that an exceedingly large amount of rural lines have been built, that huge amounts of money have been spent, and that an appreciable start has been made in this greatly needed development. The fact that less than four per cent of the farms in this country are served by such a tremendous mileage of distribution lines clearly demonstrates that to extend adequate electric service to a large portion of the farms in this country is a task involving huge sums of money. This fact is fully appreciated and it is with the complete knowledge that the adoption of a wrong policy of development would result in losses very detrimental both to agriculture and the utility industry, and which would also seriously affect other industries, that a very extensive plan of study and investigation has been made in which every angle of the extension of service to the farm and the use of such service is being carefully studied and analyzed. This work is being carried on by representatives of agricultural organizations and agricultural colleges, by agencies of the National and State Governments which have to do with agricultural problems, and by the utility industry and the manufacturers of electrical and agricultural machines and appliances.

This cooperative work is guided by a committee known as the Committee on the Relation of Electricity to Agriculture and through its efforts and the excellent cooperation of various state organizations, there have been established 17 experimental rural lines in 17 different states. These experimental lines really form field laboratories in which to carry on the study of rural electric service. By a joint study of this kind it is believed many mistakes will be avoided which would otherwise be made and, while some mistakes will probably be made, even with the precautions taken, it is believed the major mistakes will be prevented. In the meantime, rural electric service development is going ahead as illustrated by the statistics given above. Thousands of farms are being connected every month and the rate of increase in connection is growing each year.

If rural electric service is to be built on a safe and permanent basis, it must return a profit to the farmer who makes use of the service, and also make a proper return to the electric utility which supplies the service. While there is much to be learned about this new development, those who have studied it most are convinced that both of these two conditions can be met if the development is intelligently directed. By intelligent direction is meant:

(a) Creation of a new department in electric utility organizations, devoted entirely to the proper handling and solving of all rural electric service problems, and made responsible for the direction of the development.

(b) Placing at the head of this new department a man who has had training in agricultural problems and who is sympathetic toward agriculture.

(c) The development of a fair, simple, workable and complete plan under which lines will be extended and service supplied.

(d) The development of a rate schedule which will give the utility proper compensation but which is so made as to encourage increased use by the farmer.

(e) The making of surveys and maps and the collection of such information that the main trunk lines may be intelligently laid out to most efficiently serve the entire rural territory before construction work starts. (This will eliminate much rebuilding, overloaded lines, etc.)

(f) Keeping the rural department fully informed on all experimental and research work now being conducted in agricultural colleges and on the rural experimental lines in many states. This will make possible the most efficient and fullest use of electric service on the farm.

(g) Close cooperation between this rural department and farm customers.

(h) A desire on the part of the utility to supply good and adequate service at lowest cost, and a desire on the part of the farm customer to make fullest profitable use of such service.

In the following "Program for Developing Rural Service" is given a complete plan of operation of a rural department in one of the large utility companies of Wisconsin. This particular department is headed by an agricultural engineer, a graduate of the Wisconsin University, who has had about two years' experience in giving intensive study to electric service on the farm.

Program for Developing Rural Service

Successful development depends upon at least three essential factors:

A. A sound policy of building and financing rural extensions.

B. A rate schedule which fosters large use of current by the farmers.

C. A complete understanding of the rural program and of the reasons underlying its adoption, by every employee who has any direct or indirect contact with rural customers.

I. Planning the Extensions

1. A study of the location of all existing substations at which rural service lines may originate.

2. Decision as to the location of additional substations strategically placed so that the entire territory may be served to the best advantage.

3. The division of the entire territory into definite rural service areas, each to be served by its own substation. The size and shape of these areas will depend on the local conditions.

4. A basic plan or map to be followed in the building of rural service trunk lines. The first of these lines will normally extend through the most thickly-settled areas. These trunk lines should be planned with a view to serving the entire area ultimately, and all building should follow these plans.

Feeders to and stubs from these trunk lines may be built as development progresses.

II. New Rural Customers

1. First, campaign for new rural customers to be made along existing rural lines, in an effort to bring the average of customers per mile as high as possible.

2. Second, effort to be directed along existing pole lines on which it is practicable to string wires for rural service.

3. An intensive canvass of the more promising territories to be traversed by the definitely planned rural service trunk lines mentioned in Section I.

4. Definitely bringing our new rural policy to the attention of each existing rural customer, individually, and providing him with a comparison of rates based on his conditions. This work is to go on at the same time as that mentioned above.

III. Procedure

1. In securing new customers along existing lines, the rural service salesman will proceed as follows:

A. Call on prospect; explain rates and advantages of new rural policy; sign contract in duplicate.

B. Leave one copy of contract with prospect and send other to district office.

C. Make "Rural Prospect Report" in duplicate, sending one copy to local office and other to General office. This will be done whether prospect signs contract or not. Data for this report will be brought out during sales talk.

D. Make daily report showing calls made, contracts signed, miles of line covered, etc.

2. While canvassing the line for new customers, the rural service salesman will also call on each old customer and give him the opportunity to change from old to new rates. The procedure will be:

A, b, c, and d as above.

E. When canvass of line is finished, report length of line, number of old customers, number of new customers, and number of transfers from old to new rate.

3. District and local managers and all others working on rural service extension, but not specifically assigned to that work, will follow the same procedure, omitting (d), the daily report.

4. In extending rural service along existing transmission lines, the following procedure will apply:

A. Decision by engineers as to whether or not it is practicable to carry a rural distribution circuit on the same poles.

B. Estimate of costs by Engineering Department. Since the number of prospects who will become customers is not known, this estimate should show as separate item:

a. Cost of the line itself without transformers, services, or meters.

b. The cost of supplying service to a customer at some specified distance from the line, and

c. The amount to be added or subtracted for longer or shorter service lines.

C. Canvass of prospects by rural service salesmen, district or local managers, or others to create interest, and to discover how many customers may be expected. This makes possible an estimate of the cost per prospective customer.

D. Contracts and reports as detailed above.

5. The location of rural service trunk lines will be made by the Engineering Department in cooperation with the local representative and with the Rural Service Department. The location will depend upon such factors as straightness of roads, tree conditions, villages to be served, lakes, marshes, or rivers to be crossed, density of rural population, soil fertility, farm prosperity, demand for service, etc. When the location of the proposed trunk line has been fixed, procedure will be as shown above in 1 and 4.

IV. Reports to Rural Service Department

1. Daily report of rural service salesman.

2. Rural prospect report to be made in duplicate by any employee who learns of a prospect, one copy to local office, other to general office, Rural Service Department.

3. Completed canvass of rural line showing changes made.

4. Record of proposed location of rural trunk lines with cost estimate.

5. Route all work orders in any way affecting rural customers through Rural Service Department so that needed data may be taken off. Work order to show names of rural customers to be connected or disconnected, phase or service to each, and size of transformer and meter of each. Also estimated contribution to be paid by customer.

6. A complete report by each district manager of current used and bills paid each month by each rural customer.

V. Better Service

1. The closest possible cooperation between Rural Service Department and the Ripon Experimental Line.

2. Study by Rural Service Department of the reports of all electric farm projects and related articles.

3. Securing by Rural Service Department of all possible information relating to the different types and makes of all machines which are likely to be operated electrically.

4. Digests of this literature and of manufacturers' data to be supplied by Rural Service Department to district and local managers; also tables of electric consumption by different machines under various conditions.

5. A careful study of the relation between the appliances used and the resulting current consumption on the average farm. Data for this will come from the rural prospect reports and meter cards. This study will be made by the Rural Service Department and the results will be supplied to all local representatives.

6. The employment of at least one first-class electrical repair man who has a thorough knowledge of really good farming practise; this man to be furnished with a light truck and to travel the rural lines calling on every customer. He will acquaint himself with the needs of the customers, and will seek the best solutions of the electrical problems of each. He will service all faulty equipment, explain ways of making fuller use of electric service, and will carry bulbs and some of the most commonly used standard appliances to supply customers who want them. He must remember that he is a service man, not a salesman, and that he only carries merchandise for the convenience of the customers.

VI. Publicity

1. The discovery and fostering of outstanding examples of the best uses of rural service in each community. Where good farmers can be found to cooperate, each local manager should try to develop electric farms that can be used as object lessons. But this development must not be subsidized.

2. Local managers will place news items in local papers. These will report the addition of new farm customers with brief

statements of how each expects to use service, or tell of the introduction of some novel application, or give definite figures on the performance of some machines, etc.

3. A definite and unified campaign of advertising in farm papers, supplemented by a series of articles explaining the company's policy and the results that may be expected from the use of electricity.

4. Statements of bills as computed under new rates, to be sent with regular monthly bills to old rate customers who would profit by changing to the new rate. Interest on the customers' investment in the line should be included in showing this advantage.

A carefully prepared contract form has been drawn up by this company which gives definite rules under which service will be extended to new farm customers and other customers living in the country. Under these rules, the utility companies finance the rural lines up to an average cost of $400.00 per farm customer whenever the customers agree to comply with certain conditions described in rules.

This contract gives the schedule of rates used in billing as shown in the accompanying table.

RATES FOR FARM CUSTOMERS

(a) Service Charge

Transformer Capacity Required in Kv-a.	Monthly Service Charge
Not more than 1½	$5.50
Over 1½ and not more than 3	6.00
Over 3 and not more than 5	6.60
Over 5 and not more than 7½	7.25
Over 7½ and not more than 10	8.00

If more than two rural customers are served from one transformer, each of them will be allowed a discount on his service charge as follows:

Customers Served	Discount on Service Charge, Per Cent
3	20
4	40
5	50

(b) Energy Charge

For the first 30 kw-hr. used per month....5½ cents per kw-hr.
For all in excess of 30 kw-hr. used per month....3½ cents per kw-hr.

A discount of ½ cent per kw-hr. will be allowed on any bill paid within fourteen days from the date rendered. The rate is made up of a service charge sufficient to cover the fixed costs on the rural extension and an energy rate covering only generating and certain transmission costs. The energy rate is comparatively low and if the farm customer increases the use of energy very materially the addition to the monthly bill will be relatively small. This rate encourages new uses of electric service by the farmers and brings about increased use with decrease in cost per kw-hr. to the farmer. All of which is very desirable to both the farmer and the utility and brings about general satisfaction with the service.

The service charge in this schedule deals almost entirely with the distribution line costs and is based upon an average investment per distribution line of $400.00 per customer. The service charge is intended to cover return on the investment, retirement expenses, taxes, operation, and maintenance expenses. These expenses may be considered as more or less fixed expenses and do not depend upon the amount of energy consumed by the customer. Fixed costs on the investment in power plant and transmission line could be included in the service charge, but in this contract all of these fixed expenses have been included in the energy charge.

The "energy charge" is low and is based upon the production cost plus a certain portion of the fixed charges in transmission lines and generating stations. In arriving at this cost the rural customer has been given the benefit of the system load factory rather than the load factor of the farm electric load. This results in lower costs of energy but it is believed that it is the fair way to handle the situation.

The accompanying table shows the kilowatt-hours used by 1226 farmers served by a Wisconsin company. These farms are largely dairy farms. This table shows that full use is not being made of electric service on the farms listed. A number of the farms shown in the table each use more than 100 kw-hrs. per month and this demonstrates in a practical way that a large use of electric service is possible.

CLASSIFICATION OF RURAL CUSTOMERS BY AVERAGE MONTHLY USE OF ENERGY

Kw-hr. Consumed per Month	Number of Customers	Per Cent of Total Number
Less than 10	123	10
10-19	390	32
20-29	275	22
30-39	158	13
40-49	75	6
50-100	131	11
Over 100	74	6
Total	1226	100

On the various experimental lines previously referred to, the farmers are using from 100 to 500 kw-hrs. per month and the average is continually increasing. It is believed that farm customers, in three or four years, will use on the average 150 kw-hrs. per month and if this can be brought about, those who have been making a study of electric service believe that such service, sold at any fair rate, will be very profitable to the farm customers and at the same time will be a load desired by the electric public utility companies. When this condition has been brought about rural electric service will be established on a sound and profitable basis, and electric service in the country will be taken as a matter of course, much as it is now in the city.

Electrical Communication*

Report of Committee on Communication

H. P. CHARLESWORTH, Chairman

To the Board of Directors:

In presenting this report it is the aim of the Committee on Communication not so much to present a complete report of all the developments which have been made during the last Institute year in the art of electrical communication, but rather to single out those advances which it is thought will be of greatest interest to the members of the Institute.

PRINTING TELEGRAPHY

The year has been marked by a rapid growth in the use of printing telegraph apparatus by the telegraph companies, railroads, news associations for distributing news items, and by general business concerns in connection with private line business. There is a general tendency toward the operation of the apparatus at higher speeds, thus increasing the speed requirements of the line circuits and requiring the use, especially with long and complicated circuits, of repeaters which reform or regenerate the line signals.

Printing telegraphs are now being used in connection with switching arrangements, both manual and automatic. These arrangements have been found valuable for sending information from a central location to one or a number of receiving stations. A recent installation of this type consists of a number of printers controlled by automatic switching apparatus so arranged that any printer equipped with a sending keyboard can communicate individually with any other printer so equipped, or communicate with a group of receiving-only printers. Dials, similar to those used with telephone instruments, are used at the transmitting stations for setting up any desired operating condition.

The ever widening field of usefulness of printing telegraphs was illustrated by a paper on ciphering and deciphering arrangements for secret wire and radio communications read by Mr. G. S. Vernam before the Midwinter Convention of the Institute in New York last February.

In the message business of the telegraph companies there has been a marked tendency to use tape printers instead of page printers. To facilitate the subdivision of the tape into single lengths and the attachment of it to message forms for delivery to customers, effective cutting and gumming devices have been developed.

In addition to the application of tape printers to the Multiplex circuits used in trunk line service, a simplified combination of such a printer with a keyboard transmitter is coming into extensive use for branch office circuits and other short-line service. The application of these printers will probably be quite extensive due to their accuracy, traffic handling capacity, and economy. This type of printer is primarily intended for single-line operation, affording intermittent single-channel service in both directions. It also lends itself readily to use on duplexed circuits when this method is desirable. Printers of this type have a field in private offices of patrons where the amount of business handled warrants their use. Maintenance requirements are few, and the attention required is sufficiently small to make this service desirable.

"TICKER" TRANSMISSION

During the past year the automatic tape transmission system for telegraphic tickers was installed and put into operation at Cleveland, Chicago, Los Angeles, and San Francisco. Long-distance distribution of ticker service was greatly extended from New York, Cleveland, and Chicago.

A particularly note-worthy feature was the establishment of telegraph ticker service in important business centers on the Pacific Coast which heretofore obtained market quotations only by Morse on brokers' private leased wires. Full market quotations are now supplied to Pacific Coast brokers from the New York Stock, New York and New Orleans Cotton Exchanges, and the Chicago Board of Trade. Provision is also made for "dropping" the quotations at various cities along the route of the main circuit which extends from Chicago to San Francisco via Los Angeles, a wire distance of 2895 miles. New York stock market quotations reach the brokers on the Pacific Coast in 30 to 45 seconds from the time that they appear on the tickers in Wall Street.

The system developed for this and similar services elsewhere includes modifications of the two-channel, Multiplex printing telegraph apparatus and repeaters suitable for use on the long lines involved.

The transmitters are controlled by perforated tapes similar to those used in other automatic telegraph systems. Instead of the more familiar five-unit code, a six-unit code is employed, the sixth pulse of each character serving to distinguish between letters and

figures. The receiving instruments at customers' offices are self-winding tickers of a type already widely used in Eastern cities.

The output of the channel printer system in characters per minute per channel is the same as that obtainable with self-winding ticker systems used on shorter circuits having but one channel.

Submarine Telegraphy

The great success of the new type of submarine telegraph cable loaded with permalloy that was mentioned in last year's report has led to the rapid extension of this type of cable, and during the year five important telegraph cables of this type were under construction. The technical features of this type of cable were described in a paper by Mr. Oliver E. Buckley which was presented at the Convention last June and which appeared in the August Journal.

Machine Switching Telephony

With the continued steady growth in the application throughout the country of machine-switching telephone apparatus have come further developments in this form of apparatus. In the panel system, which is the type of system used for large cities, a simplified form of tandem switch has been developed by which, after one selection at the calling office, the final selection of the called office can be made by apparatus located at a distance from the originating office, and used to collect traffic from a number of offices routed over common groups of trunks. This results in a material saving in the trunk plant.

A more efficient method of associating a sender with the calling subscriber has been developed. This results in an appreciable saving in the number of senders required, uses more economical apparatus, and reduces the number of types of apparatus required in an office.

In the step-by-step system, which is the type usually used for the medium and smaller sized cities a line-finder system has been developed which is similar in principle to that being used with success in panel offices. This employs the same selector that is used in the rest of the switching train, effects an improvement in service to the subscriber, and lends itself more readily to efficient equipment layout.

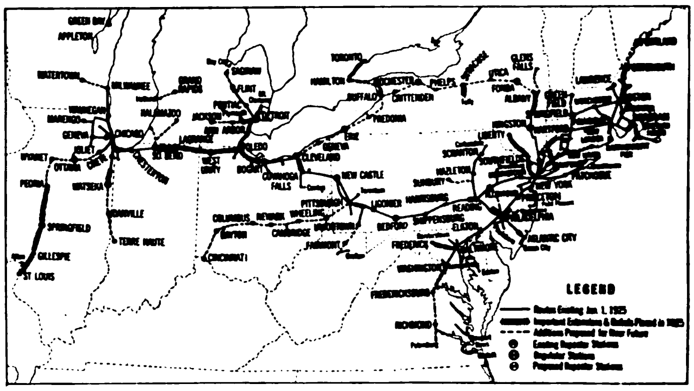
A machine-switching tandem system, employing step-by-step equipment, has been developed for completing toll calls within a 50-mile radius of any given central office area. All calls completed through this system are handled directly by the originating operator over dialing trunks. A tandem system of this kind probably will find its principal application in areas employing step-by-step machine-switching equipment. An installation of this type recently has been put into service in Los Angeles and serves some 75 central offices having a total of approximately 400,000 subscribers. The principal new engineering feature of this system is the means which was developed for dialing and signaling over phantom toll lines.

New types of frames for mounting step-by-step equipment have been developed which take advantage of the ceiling heights ordinarily found in central office buildings, thus effecting a material reduction in floor space requirements.

A cordless "B" switchboard has been developed for completing calls from manual offices to machine offices where the number of manual offices involved makes the use of dialing devices at the manual offices prohibitive in cost. This switchboard employs new trunking principles which result in very efficient and simplified operating equipment.

Telephone Toll Cables

An event of prime importance during the year was the completion on August 11 of the telephone toll-cable system connecting New York and other Atlantic Seaboard cities with Chicago. This system of cables runs from Chicago through South Bend, Toledo, Cleveland, Detroit, Pittsburg, and Harrisburg to Philadelphia and New York, connecting with the cable system extending from New York to New Haven, Hartford, Springfield, Providence, Worcester, Boston, and Albany, and from Philadelphia to Baltimore and Washington. Extensions of this cable westward from Chicago carry the toll-cable system to Milwaukee, and by the end of this year the system will extend to Peoria, Springfield, and St. Louis. Numerous shorter branches carry this network to many other points near the large centers mentioned.



Toll Cable Routes in Northeastern Section of the Country

In addition to this very extensive network in the northeastern part of the country, smaller networks are starting in other parts of the country, notably in various parts of the Pacific Coast and in Florida. The rapidity of growth of this type of telephone plant is illustrated by the fact that during the year 1925 over 1000 miles of toll cable were placed in service, and during the year 1926 more than 1500 miles will be installed. The map reproduced below shows the routes of the present and proposed toll cables.

The possibility of providing satisfactory telephone transmission over very long circuits in cable has come about through a series of remarkable developments in telephony which have been discussed from time to time before the Institute. During the year the network mentioned above was the subject of a paper presented before the New York Section in December by Mr. J. J. Pilliod, and was discussed at other section meetings.

The development of toll-cable networks means a great deal in improving and increasing the service given to the public. Practically the entire country is subject to severe sleet storms from time to time and toll cables furnish a means for providing great security against interruption from such storms or other weather conditions. Furthermore, they furnish a practical solution for meeting the very great demands for service between large urban centers of the country. A single cable contains between 200 and 250 telephone circuits and would require five or six open-wire toll lines with former methods of construction, the largest number of circuits which can be provided by this means; furthermore, furnishing means for supplying circuits so liberally as to give a faster service. As indicative of the increased facilities provided, it may be mentioned that the New York-Chicago toll-cable system contains about 510,000 miles of wire, while at the time this project was started, the facilities for serving the corresponding points consisted of less than 100,000 miles of open wire.

In last year's report reference was made to certain papers describing the development of telegraph systems suitable for use in long telephone cables. The application of these systems has been considerably extended during the past year. The voice-frequency carrier system is of special interest, since, through the development of apparatus for separating to a very high degree currents of different frequencies, it has become possible to operate 12 independent telegraph circuits over a single telephone cable circuit, each of the 12 circuits using a different frequency ranging from 425 to 2300 cycles per second. There are now in operation about 25,000 channel miles of telegraph circuits operated by this system in the telephone cable plant.

Radio Telegraphy

A new radio telegraphy service between the Dutch East Indies and San Francisco has been established, and a new service from New York to Holland has been introduced for handling through traffic from Java.

The work of decreasing the use of spark transmitters with their corresponding interferences, commenced in 1924, has progressed rapidly to such an extent that over 150 American merchant ships are now equipped with tube transmitters.

The use of the radio direction finder for navigation is rapidly increasing and has passed the experimental stage. The Great Lakes are leading in this respect, due to the demonstration of the particular value of this apparatus in the difficult navigation problems inherent in the Great Lakes.

Transatlantic Radio Telephony

The development work which has been in progress during the past few years on transatlantic radio telephony reached a point of considerable interest last winter in the attainment of two-way telephonic conversations. In the earlier tests, telephonic transmission had been but one-way, from the United States to England, with the study of transmission of radio waves in the reverse direction being made by the utilization of radio telegraph stations in England. Two-way talking was made possible the winter of 1925-26 by the completion of a transmitting station by the British General Post Office. The British radio telephone transmitter is, in general, similar to that employed on the American side. Both transmitters are of the carrier-suppression, single-side, band type, which makes the maximum use of the transmission power and which minimizes the frequency band which is required. Receiving on both sides is carried out by means of directional receiving antennas of the wave-antenna type. Reception on the American side has been further improved by establishing a receiving station at a higher latitude where the atmospheric interference is less, located at Houlton, Maine. The Houlton reception is extended into New York by means of wire telephone circuits. Likewise, the voice currents originating in New York are transmitted to the Rocky Point transmitting station over wire circuits. Similarly, in England the radio transmitting and receiving stations are connected into London by telephone circuits. In this way, an integral two-way circuit is established with New York, and London as the terminals.

The carrying on of two-way talking tests between England and the United States created much general interest and arrangements were made to enable a group of American Press representatives in New York, and a similar group of English newspaper men in London, to participate in the tests by conversing with each other. These tests represent the first time that groups of people have been able to converse with each other across the Atlantic.

Papers by Messrs. A. A. Oswald, J. C. Schelleng, and R. A. Heising, describing important technical features of the apparatus used for transatlantic radio telephony were published in the June 1925 *Proceedings* of the Institute of Radio Engineers.

Radio Propagation Tests

A great deal of activity has been shown in studying the properties of the medium, intervening between transmitter and receiver, through which the radio waves must pass. This information is essential before we can utilize, to the best advantage, this remarkable but eccentric medium which nature gives us.

Extensive propagation tests have been reported on

long, medium, and short wave lengths, together with a large amount of theoretical work towards explaining and correlating the apparently contradictory behavior found in different parts of the radio spectrum. This work has confirmed the existence of a positive ionization gradient in the upper atmosphere, postulated independently, many years ago, by Kennelly in this country and Heaviside in England.

The Naval Research Laboratory published the results of experiments which indicate that short waves may, in effect, hurdle the first few hundred miles of their journey and be received at a distant point with a much greater strength than would be expected from the past experience with long waves. In the range of frequencies under exploration (down to about 30 megacycles, or 10 meters) the "skipped" distance appears, in general, to increase with increase of transmission frequency and to be greater at night-time than at day-time. These results have been confirmed by other experimenters. Theories have been proposed (among others, by Baker and Rice in a paper presented before Midwinter Convention of the A. I. E. E., 1926) to explain these phenomena which assume that waves received at a distance are deflected downward from some upper ionized region of relatively low index of refraction and of low attenuation.

The observed indications of rotation in the plane of polarization and directional errors find a qualitative explanation when due account is taken of the fact that the earth's magnetic field, acting upon the free electrons, will change the velocity of the wave and produce rotation. This effect is especially marked in the vicinity of 214 meters, which corresponds to the resonant frequency of an electron in the earth's magnetic field.

Careful investigations of fading and signal distortion, so exasperating to the broadcast listener, have shown that they are closely related to the high degree of frequency selectivity exhibited by the radio medium.

During the total eclipse of January 24, 1925, many observations were recorded which further tended to confirm the recent electron dispersion theory of the radio medium.

An observed variation of signal strength during magnetic storms is also significant. Here the effect is a reduction of the normal signal strength by night and an increase above normal by day.

Increasing use is being made of the short wave range of frequencies as is evidenced by the continued increase in the number of short wave licenses issued to commercial concerns. Experimental work indicates the possibility of twenty-four-hour telegraph service with short waves over distances of several thousands of miles. The transmission varies largely with the time of day, however, one frequency transmitting much better for one period of the day and another frequency for another period, so that the use of several wave frequencies appears to be required to give uniform operation.

Radio Broadcasting

Continued improvement has been made in radio broadcasting on both the receiving and the transmitting sides. The receiving set improvements are, in general, characterized by better quality of reproduction, which means higher grade amplifiers and better loud speakers; but there is still much to be desired in these respects in receiving sets as a whole. The fact that the reliable, high-quality service range of the average radio broadcast transmitting station is relatively short is being more generally recognized and is leading to a more extensive use of long distance wire lines for enabling good programs to be made available at a number of widely separated broadcast stations, and is leading also to the use of greater power in transmitting. As many as 17 stations, spread over the northeastern quarter of the United States, are now regularly supplied for a portion of their time with programs transmitted over special long-distance wire circuits. A number of stations are now transmitting with five kw. power, and one station which is capable of transmitting with as much as 50 kw. has been established during the year.

Another important improvement in radio transmitting stations introduced during the year is the use of master oscillators with piezoelectric frequency control for the purpose of reducing quality distortion in the received signals. In general, there was a considerable improvement in the maintenance of the frequency assignments of broadcast stations, due to a more general appreciation of the need for frequency stability and to the efforts of the Radio Inspection Service in checking up conditions and of the Bureau of Standards in the work of frequency standardization.

The problem which exists in the regulation of radio, in the general public interest particularly in the allocation of wave bands, has been reflected in submitting to Congress several bills designed to strengthen the Government's control of radio, and by the holding of the Fourth National Radio Conference at Washington during the fall of 1925. This Conference recognized the fact that the number of transmissions which can be accommodated in the range of frequencies available for broadcasting is definitely limited, and recommended that the Department of Commerce undertake to limit the number of broadcast stations to be licensed.

Electrical Transmission of Pictures

The commercial service for the transmission of pictures by wire between New York, Chicago, and San Francisco, has continued throughout the year. The results have been promising and it has been decided to add five more complete stations to the picture-transmission network. This extension should enable a thorough test to be made of the commercial demand for this type of service.

An interesting experiment was conducted for the U. S. Signal Corps, in October 1925, when pictures

were taken from an aeroplane over Fort Leavenworth, Kansas, developed on the plane, dropped by means of a parachute, and transmitted from Fort Leavenworth to New York, Chicago, and San Francisco, simultaneously. The entire experiment was so successful that army officers in New York City viewed the picture 29½ minutes after the snapping of the camera on the plane at Fort Leavenworth, approximately 1500 miles away by wire. This is an indication of the usefulness of telephotographs for war purposes.

During the year from March 1925 to 1926, a series of tests of radio transmission pictures has been conducted between Carnarvon (Wales), San Francisco, Honolulu, and New York. Specific mention should be made of the pictures sent by radio from Honolulu to New York during the Naval maneuvers of our fleet there in May 1925. As a result of the successful completion of this experimental work, commercial service has been established between England and New York and also between Hawaii and San Francisco.

Inductive Coordination

Last year, the report of the Committee announced the formation of the American Committee on Inductive Coordination, embracing representatives of all wire-using utilities interested in this problem. During the year, the committee has issued a very complete and extensive bibliography of publications bearing on inductive coordination. This bibliography includes not only American, but also foreign references and contains a total of about 900 items. It is expected to be of great value to all concerned with inductive coordination work. Another item of interest in this field is the issuance of a report by the joint, general committee of the National Electric Light Association and the Bell Telephone System, covering the principles and practises adopted by those organizations for the joint use of wood poles by supply and communication companies.

During the year this joint general committee continued its progress in research work on a large number of specific problems in inductive coordination. The study of these problems has been facilitated by the development of improved measuring apparatus and methods particularly adapted to the wave analysis of power-circuit voltages and currents and of induced voltages and currents in telephone circuits.

Two papers dealing with the subject of inductive relations between power-distribution circuits and telephone circuits were presented at the Seattle Convention in September, in connection with a symposium on power-distribution.

Telephone Service for the Deaf

Another interesting telephone development relates to improved service for deaf people. Many partially deaf people, who have difficulty in hearing ordinary conversations, use the telephone with ease. Others, who are somewhat more deaf, however, have not been able heretofore to use the telephone. In order to make the telephone service available in these special cases, apparatus which greatly increases the volume of sound received has been developed for the use of deaf people. Although in cases of extreme deafness, no amplification of sound, however great, makes hearing possible, this new device makes it possible for many people of impaired hearing who would otherwise be unable to use it to obtain telephone service. The apparatus is designed, of course, only for those having impaired hearing.

Characteristics of Speech

The work carried on by telephone research engineers, in the study of the characteristics of speech, has continued to produce important and interesting results which have been described in a number of publications during the year. Of particular interest is the paper published in the A. I. E. E. Journal for March 1926, by Messrs. Maxfield and Harrison entitled "Methods of High Quality Recording in Reproducing of Music and Speech Based on Telephone Research." This paper tells of the application to the improvement of phonographic reproduction of speech of some of the methods developed in the study of the quality of telephone transmission.

Loading of Telephone Circuits

The year 1926 marks the completion of the first 25 years of the application of loading to telephone circuits, in the form of inductance coils inserts in the line at periodic intervals. A paper presented by Shaw and Fondiller at the Midwinter Convention reviewed the progress which has been made in this country, in both the development and application of loading, covering particularly, the last 15 years. The outstanding developments in that period are the compressed-powder iron-dust core material, the loading systems for the long toll cables and the more economical systems for local exchange area trunk circuits. The extent of the application of loading is indicated by the estimate given in that paper, of 1,250,000 loading coils in this country, as of January 1, 1926, and by the expectation that this number will be doubled by 1930.

Fire-Alarm, Police-Signal, and Train-Control Systems

The National Fire Protection Association has continued its work of standardizing and improving emergency signalling systems. At its last annual convention, completely revised "Regulations for Municipal Fire Alarm Systems" and partially revised "Regulations for Protective Signalling Systems" were adopted, and work for the further revision of the latter regulations has been carried on throughout the year.

The International Association of Municipal Electricians has continued the compilation and promulgation of standard specifications for wires and cables for municipal signalling. Important additions were made to these specifications during the past year.

Another important development has been the completion of arrangements by some leading railroad systems for automatic train-control systems. This promises to become a very important field of operation.

The field of police emergency signals and traffic signals is constantly growing in importance. Many cities are now installing an elaborate system for one or both of these. In some cases, the systems include a combination of police-alarm, fire-alarm, and traffic signals, whereby officers on traffic duty may receive due warning of fires and escape of bandits in automobiles, and thus facilitate the movement of fire apparatus in the one case and block all traffic in the other. Further advances have been made also in the installation of extensive modern manual fire-alarm systems in a number of important cities.

Can the University Aid Industry?

BY BENJAMIN F. BAILEY[1]

Fellow, A. I. E. E.

AT first the author was inclined to reverse the title and make it read "Can Industry Aid the University?" There is no doubt in his mind that the engineering professor should have active and continuous contacts with industry. It is generally agreed that it is impossible for a school to teach engineering applications in detail. The field is altogether too broad and the variety of positions which students fill after graduation is so great that any attempt to fit a man to fill a particular position upon graduation must result in failure. The university can and should attempt to give a thorough foundation in the fundamentals underlying engineering and if this is well done it will require easily all the available time.

From this it might seem that if a teacher is well grounded in the fundamentals, he has all the necessary qualifications. To keep the interest of the student, however, and prepare him for his life work, the application of these principles to specific problems must be continually emphasized. If a teacher lacks definite personal knowledge of at least one field of engineering practise, he is seriously handicapped in his attempts to show how the fundamentals of physics, mathematics and economics may be applied to engineering practise. Moreover, the interest and ambition of the student is more easily aroused if he feels that his instructor has personal knowledge of the things about which he is talking. If the proper attitude on the part of the student is secured, the other problems of engineering education will largely take care of themselves.

Another reason for encouraging the teacher to make practical use of his knowledge and experience is that he may increase his income. Everyone knows that the salaries paid university professors are, in many cases, low as compared with the incomes that the same men could earn in industry. Under present circumstances in the colleges if the best teachers are to be secured and held there must be some way for them to earn something outside of their university salaries. Those who have been responsible for the conduct of departments of instruction have many times had the experience of losing their best men when they were offered twice as much salary by industry.

The author believes that there is a growing spirit of cooperation between industry and the universities. This is due to a number of causes. Doubtless the work of college professors during the war had a great deal to do with it. There are numerous instances of supposedly impractical professors who turned out to have the finest kind of executive ability and who were able to apply their theoretical knowledge to practical affairs upon short notice.

The decrease in the relative number of consulting engineers may have helped to foster this cooperation. The fact that the customer can obtain excellent engineering advice free from most of the large electrical companies has tended to deter men from becoming consulting engineers. Many problems, however, come up which cannot well be handled by reference to some manufacturer and if consulting engineers are not available, the work is likely to be turned over to a teacher of engineering.

Relatively, at least, the importance of the individual inventor seems to have decreased. It is coming to be more and more apparent that many problems are of the type best handled by scientists rather than by inventors and again the work is likely to be turned over to a teacher of engineering.

A third reason is the notable work accomplished by the research laboratories established by many of the larger electrical companies. The pronounced commercial success of many of the devices developed in such laboratories has shown the value of scientific services to the smaller manufacturers.

Whatever may be the cause, it seems to be a fact that so much work of a scientific nature is brought to the universities that it may not be long before the handling of this work will constitute a real problem.

For a great many years past, the Engineering Department of the University of Michigan, under the leadership of Dean Cooley, has encouraged the faculty to make contacts with industry. The question as to

1. Professor of Electrical Engineering, University of Michigan, Ann Arbor, Mich.

Presented at the Regional Meeting of District No. 5 of the A. I. E. E., Madison, Wis., May 6-7, 1926.

how far this sort of work should be encouraged was once raised and the regents of the university passed resolutions intended to clarify the situation. These were to the effect that the faculty of the Department of Engineering was encouraged to accept work of the proper character to as great an extent as possible without interfering with their regular work of instruction. They were given permission to use their offices and the laboratory facilities of the university for the carrying on of such work. It was clearly indicated that the work undertaken must be of more than routine character and that the amount and type of such work must meet with the approval of the Dean of the department.

The work offered to the university usually falls in one of three classes.

a. Routine tests of materials and apparatus
b. Engineering advice
c. Research problems

A. Work of the first class has been discouraged, although not entirely prohibited. It frequently happens that a manufacturer wishes a particular test made and no other agency is prepared to do the work as quickly or as economically as the university. Not infrequently the university is asked to undertake work of this character because an absolutely impartial test is desired. With these facts in view, it does not always seem wise to refuse work of this character. When it is possible, however, it is turned over to the younger men to whom the experience is probably of some value.

B. The type of work called *engineering advice* requires a distinctly higher grade of ability. A number of professors have performed notable services in connection with appraisals of railroads, telephone companies and power plants, by acting as expert witnesses in patent suits, by advising with municipalities regarding important bridges, roads and other public works, and by acting as consulting engineers to various manufacturing plants, as well as in numerous other ways. Many of these contacts have resulted in men being enticed away from the university by the offer of large salaries. In some cases these men have been lost permanently to the teaching profession; in other cases "leave of absence" for one or two years has been granted and the man has willingly returned to resume his university duties.

C. A considerable amount of research work has been carried out also; sometimes this is done for pay at the request of some manufacturer, but more often is undertaken merely on account of real interest in the work or with the hope that a good piece of work will result in promotion. Naturally most of us tend to concentrate on work which is paid for in cash as well as reputation, rather than on that which is paid for in reputation only. Nevertheless, some notable work has been done and if time were available, it would be interesting to list some of the papers published, dealing with research work accomplished at the University of Michigan.

Interest in research, particularly in applied research, has been stimulated by the establishment of the Department of Engineering Research in 1920. Some three or four years prior to this time, a group of engineering alumni proposed that the university establish such a department, and this was brought to a head a little later by a request from the Michigan Manufacturers Association. The manufacturers felt very strongly that such a department would be of distinct assistance to the industries of Michigan and other states, and that, in turn, industry might help the university. These concerns pointed to the large sums of money spent in agricultural research and, while admitting that every penny of this was well spent, insisted that money might be spent to equally good advantage to aid industry. The department has had a steady growth and the amount of work done has increased, until this year it is expected that approximately $100,000 will be paid into this department by industry for services rendered.

In establishing this department, a large number of perplexing problems had to be met. One of the first referred to the fees which should be charged for work done. It was universally agreed that the manufacturers requesting services should pay for them. The person doing the work receives a compensation approximately equal to that which he would receive for the same work done for the university. In addition an overhead charge of from 20 to 50 per cent is made to cover, at least partially, the use of laboratories and equipment and the cost of shop service, electricity, gas, air or other sources of energy.

The question of the character of work to be undertaken also demanded serious consideration. The policy of the department is to discourage routine tests as much as possible. If requests for such work come in, the inquirer is advised of the existence of commercial laboratories capable of doing the work requested. If it appears, however, that, fors ome reason or other, the work cannot be so satisfactorily accomplished elsewhere, the Department occasionally accepts such work. The percentage of tests in which no critical judgment is required, however, is very small.

On the other hand, the department fosters work of a research character and work in which judgment and engineering experience is definitely required.

The question of patents has proved to be perhaps the most perplexing of all the problems confronting the department, and the policy to be adopted has not yet been entirely settled. One proposal made was that if, in the course of a research, patentable inventions were made, the patent or patents were to be taken out at the expense of the university and thrown open to the use of the public without charge. To most of the members of the department, this did not appear to be a wise policy. It seemed that the manufacturer who supplied the funds for the investigation and the man who made the invention both deserved some reward. Since it furnished the facilities, the university, was also entitled to consideration. Moreover, if a patent were thrown

open to anyone it is quite likely that no one would use it. The reason, as most engineers know, is that when an invention has been made, the trouble has just started. Almost invariably it is necessary to invest a large sum of money in developing the invention, putting it in form for economical manufacture and educating the public to use the new product. Since proportions and designs cannot be protected by patents (to say nothing of the desire aroused by advertising to possess the new article) a manufacturer might expend large sums in developing an invention and then be at the mercy of anyone who wished to steal the results of his efforts. Under such conditions a meritorious invention might never be put to practical use.

It was considered inadvisable also to allow patents taken out in the course of an investigation to be assigned exclusively to the manufacturer financing the work. An invention made in the course of research would be in the nature of a by-product and, in general, would not be expected when the work was started. It was thought that if some invention of great value should sometime appear, the university might be severely criticized for allowing it to fall into the hands of a single individual or corporation.

The plan tentatively adopted provides that patents may be taken out by the inventor with the consent of the Board of Regents and at the expense of the person financing the investigation. All inventions are to be assigned to the university with the understanding that the manufacturer involved will have first consideration in the case of the sale of the patent or the granting of licenses under it. It is also understood that in case an invention prove valuable, the inventor may expect to profit to some extent. A number of patents have been applied for but in no case has the point been reached where this problem has had to be frankly faced. Under the present scheme the manufacturer is obliged to pay the expenses of taking out the patent and has no definite assurance as to what interest he will have under it. Neither has the inventor any assurance as to what returns he may expect.

The actual work of investigation under the Department of Engineering Research is carried out very largely by the teaching staff of the Engineering Department. There are, however, a few men who devote their entire time to this work. These men hold similar rank to men of the same attainments in the engineering college. The titles used are investigator, associate investigator, assistant investigator, research assistant, and assistant.

One of the first questions of policy to be settled when the Department was organized was whether or not a manufacturer might obtain data for his exclusive benefit. It was definitely determined from the first that the results of all investigations were to be made available ultimately, but publication is necessarily deferred for some time. Within the past year, the department has begun the publication of a bulletin in which the results of investigations are available to anyone interested.

The department is now undertaking the direction of a Meter Testing Laboratory in the Department of Electrical Engineering. This is somewhat of an extension of the original scope of the work of the department since the work of checking meters and instruments can hardly be considered as research. This laboratory was established at the request of the Detroit Edison Company and the Consumers Power Company as a convenience to the Public Utilities of the State. It was thought that the actual administration could most readily be carried out through the Department of Engineering Research. When this laboratory is in operation, the Public Utility Companies will be able to obtain prompt tests upon the accuracy of voltmeters, ammeters, wattmeters, current and potential transformers, and rotating standard watthour meters.

It is believed that the future work of the Department of Engineering Research will lie largely in cooperative research. In Michigan, there are a number of industries each carried on by a large number of manufacturers. Familiar examples are the furniture industry, the beet-sugar industry, the automobile industry, the paper industry and many others. In some of these, very little is done in the way of research, and it would seem that the manufacturers could well afford to cooperate to the extent of financing extensive research work. Some progress has been made in this direction, but naturally it will require time to interest enough manufacturers in each line to make the scheme a success.

The department also plans, as far as its finances will permit, to carry out researches in both pure and applied science upon its own initiative. A number of problems immediately suggest themselves which might well be the basis of extensive work and which promise ample returns for the money invested. In the case of some of these problems no one manufacturer is sufficiently interested to finance the work with the understanding that all results will be public property. Before very much can be done along these lines the department will have to secure more adequate financial support. At present, the State of Michigan spends, yearly, about $250,000 upon agricultural research. Every penny of this is undoubtedly justified. The value of the agricultural products in the State of Michigan is approximately $600,000,000 per year, but the value of the manufactured products is $3,500,000,000, or nearly six times as much. If engineering research received financial support on the same basis as agricultural research may it be seen that there would be approximately $1,500,000 available per year. It is to be hoped that in the near future this work will come somewhere near to securing the support it deserves.

Some mention of several notable investigations already undertaken by the department may be of interest.

Natural Lighting. Work has been going on for about

two years upon the subject of day lighting. Apparently very little had previously been done along this line and the importance of the work is obvious.

Natural Ventilation. A similar investigation was carried on to determine the extent to which ventilation occurs naturally in factory buildings. This is another subject upon which little or no data were available.

Bearing and Gear Noises. Some very interesting work has been done upon the sources of noises in machinery and the methods of measuring noises. A very ingenious device has been developed by which quantitative readings of noise may be made and some advance has been made in locating the source of noises in roller bearings and gears.

Single-Phase Motors. Work has been carried on for about three years upon the subject of single-phase motors, and considerable progress has been made in developing a new type of single-phase motor.

Cutting of Metals. A fundamental research is in progress upon the art of cutting metals with particular reference to milling cutters. A method has been developed for determining accurately the forces involved in action of a single tooth of such a cutter.

Industrial Waste Disposal. This work was undertaken at the request of the City of Flint, where the subject of waste disposal has assumed great importance.

SUMMARY

The writer believes that a distinct advance has been made within the last few years in the relations between the University and Industry. It is hoped and believed that this tendency to cooperate will continue and will be of great advantage to both parties to the transaction.

DUCTILE ARC WELDS

A step forward in the utilization of the heat of electric arcs in the joining of metal parts or the building of metal structures—another step toward the day when the pounding, noisy riveter will resign in favor of the quiet electric welder for most work—has been taken in the development of two methods of producing ductile welds. The one was developed by Dr. Irving Langmuir in the Schenectady research laboratory of the General Electric Company; the other almost simultaneously in the Thompson research laboratory of the company at Lynn, Massachusetts, by Peter Alexander.

In both processes, while the welding is being done, air is excluded from the metal at the joint by means of a bath of hydrogen or other suitable gas. The formation of oxides and nitrides which are objectionable, in the weld metal, is thus prevented; the fused metal is as strong and ductile as the original metal.

Dr. Langmuir's study of lamp filaments in hydrogen was a theoretical investigation. Now, fifteen years later, the results have been applied in a different field—in the development of a new and improved method of welding.

Continuing the theoretical investigation, Dr. Langmuir found that more atomic hydrogen was formed by passing a powerful electric arc between tungsten electrodes in hydrogen at atmospheric pressure. By directing a jet of hydrogen from a small tube into the arc, atomic hydrogen could be blown out of the arc, forming an intensely hot flame of atomic hydrogen burning to molecular form and liberating about half again as much heat as does the oxy-hydrogen flame.

By using such a flame of atomic hydrogen, iron can be welded or melted without contamination by carbon, oxygen or nitrogen. Because of the powerful reducing action of the atomic hydrogen, alloys containing chromium, aluminum, silicon or manganese, can be welded without fluxes and without oxidation. The rapidity with which such metals as iron can be melted exceeds that in the oxy-acetylene flame, so that the process promises to be particularly valuable for welding. Either alternating or direct current can be used with this process.

In testing welds made by this process, the welded portions have been twisted and bent double without cracking or otherwise being injured. Such results have not been attained with the ordinary arc weld, since such welds are usually brittle because of the presence of nitrides or a thin film of oxide or scale, avoided in the new process by the presence of the hydrogen.

The process developed in the Lynn laboratory is based on the utilization of the chemical and physical properties of hydrogen and other gases in the molecular state. This process aims primarily at the prevention of the formation of the nitrides and oxides in the arc-deposited metal, which limit the ductility of the usual arc welds.

In this process the arc is struck between the metallic wire or carbon used as one electrode and the plate or work to be welded used as the other electrode. The crater of the arc is always on the work to be welded. The gaseous atmosphere is supplied in the form of a stream around the arc. Pure hydrogen, water gas, hydrogen-nitrogen mixtures, anhydrous ammonia, methanol vapor and some other gases can be used, according to the nature of the work. The process makes arc welding more efficient, and suitable for fields which at present are out of its reach. Low-carbon steel, alloy steels, and most of the non-ferrous alloys can be welded with success by this process in suitable gaseous mixtures.

The Use of the Dynamometer Wattmeter for Measuring the Dielectric Power Loss and Power Factor of the Insulation of High-Tension Lead-Covered Cables

BY EVERETT S. LEE*

Associate, A. I. E. E.

***Synopsis.**—The use of the dynamometer wattmeter for measuring the dielectric power loss and power factor of cable and capacitor insulation is not new, but dates from about 1890.*

Dynamometer wattmeters as available today are suitable for making these measurements. Care and attention must be given to their application.

The usual methods of application are:

1. Compensated dynamometer wattmeter method, with air capacitor,

2. Inductance variation method (phase-defect compensation method), with air capacitor,

3. Series resistor and wattmeter method,

4. Resonance wattmeter method.

Comparative measurements of dielectric power loss and power factor of cable samples indicate that results are being obtained with the dynamometer wattmeter wherein the probable departure from the true value is within from 10 to 20 per cent.

There is need for an effective means of standardizing any measuring equipment. Study of the calorimeter method for this purpose seems desirable.

* * * * *

INTRODUCTION

PRESENT-day purchase specifications for high-tension lead-covered cables contain clauses limiting the values of the dielectric power loss and power factor of the insulation; these properties must therefore be measured either on the factory product in reel lengths, or on samples cut therefrom, or on both as may be specified. The dielectric power loss is the total power consumed in the insulation, and is expressed in watts. The power factor of the insulation is the ratio of the dielectric power loss to the product of the voltage across the insulation in volts and the resulting total current in amperes. The measurement of the dielectric power loss and power factor of the insulation therefore involves either (1) the measurement of the power, voltage, and current from which the power factor may be calculated; (2) the measurement of the power factor, voltage, and current from which the power may be calculated; or (3) the measurement of the power and reactive volt-amperes from which the power factor may be calculated.

The range of the values to be measured for present-day, single-conductor cables up to 43-kv. rating, conductor to sheath, (75-kv. between lines, three-phase), and three-conductor cables up to 33-kv. rating between treated paper-insulated conductors, is shown in the following:

Values for samples, 10 ft. of lead

Range of Impressed Voltage, 5 to 100 kv.
Range of Temperature, 20 to 100 deg. cent.
Dielectric Power Loss, 0.05 to 25 watts
Leading Current Power Factor, 0.002 to 0.10
Charging Current, 1.5 to 20 mil-amperes

For factory lengths which frequently extend up to 750 ft., the values of dielectric power loss and charging current are proportionately greater for the same voltage. The values of power factor remain the same.

The measurement of such low values of power and and power factor over a relatively wide range of voltages extending to high values is not simple, but requires special equipment. The instruments available for such measurements are the dynamometer wattmeter, the electrostatic wattmeter, and a-c. bridges. It is the object of this paper to discuss particularly the use of the dynamometer wattmeter in making these measurements.

THE DYNAMOMETER WATTMETER

A dynamometer wattmeter is one which depends for its action upon the electromagnetic interaction between sets of fixed and moving coils, one set being traversed by the circuit current (or a current proportional to the circuit current) and the other set by a current proportional to the circuit potential. The external resistor is usually considered as an integral part of the instrument potential circuit. Most present-day wattmeters for switchboard and portable use are of the dynamometer type, the moving coils being supported between jeweled bearings. For measurements of dielectric power loss in cable insulation where the power to be measured is of very low value, a sensitive dynamometer wattmeter is used in which the moving coils are delicately suspended by a fine filament. The deflections are read from a scale set at some distance from the instrument and traversed by a light beam reflected from a small mirror carried on the moving system. There are usually two complete elements connected in series, one element being mounted above the other, the upper and lower elements being of opposite polarity thus making the

instrument astatic so as to eliminate errors due to external magnetic fields. Such an instrument is called an astatic reflecting electrodynamometer wattmeter, but it is usually referred to in connection with cable testing as a dynamometer wattmeter. A commercial form of an astatic reflecting electrodynamometer wattmeter is shown in Figs. 1 and 2.

Use of the Dynamometer Wattmeter

The use of the dynamometer wattmeter is not new, but on the contrary is quite old. Its introduction is generally attributed to Professors Ayrton and Perry in 1881. In 1899, Rosa and Smith[1] published results of their measurements of dielectric power loss and power factor of capacitors using a resonance wattmeter method and using a calorimeter method, and following these in 1904 Dr. Rosa[2] published his further work in measurements made upon capacitors and circuits of low power factor using a dynamometer wattmeter with different methods of application, some of which are employed today in measuring dielectric power loss and power factor of cables. In 1901, Dr. C. V. Drysdale[3] described a dynamometer wattmeter of his own design, and at that time wrote the theory of

the a-c. wattmeter which is still in use today. In the same year Dr. Drysdale[4] described the results of his measurements, using his dynamometer wattmeter to determine the dielectric power losses in capacitors and cables. At about this same time, instruments such as shown in Figs. 1 and 2 were developed and have been improved with the progress of the art.

From these early days to the present it is possible to trace the use of the dynamometer wattmeter for measuring dielectric power losses in capacitor and cable insulation through the writings of such men as Heinke[5], Potts[6], Mordey[7], Apt and Mauritius[8], Semenza[9], Humann[10], Hochstaedter[11], Shanklin[12,13], Farmer[14], Renneson[15], Frigon[16], Barbagelata and Emanuele[17], Granier[18], Marbury[20], and Bruckman[21], and still this list is quite incomplete. The work by Carrol[19] and others in measuring corona losses in high-voltage transmission lines deserves mention in this regard.

The use of the dynamometer wattmeter for these measurements is thus seen to be quite firmly established. The theory of the instrument has been adequately stated by several writers[27,28,29]. Instruments are commercially available in which the inherent errors have been reduced to the minimum consistent with good instrument design. The problem in connection with measurements of dielectric power loss and power factor of cable insulation becomes, therefore, mainly a problem of correct application.

Application of the Dynamometer Wattmeter

In applying the dynamometer wattmeter to the measurement of dielectric power loss and power factor of cable insulation, means must be provided for supplying current to the current circuit of the dynamometer and potential to the potential circuit of the dynamometer, so that these will represent the cable-circuit current and potential in known proportionate value and in phase. Dynamometer wattmeters are usually supplied with a current circuit of suitable rating for direct connection into the cable circuit. If this condition is

1. For all references see Bibliography attached to original paper.

not satisfied and a shunt is required, then compensation must be made for any difference that may exist between the phase angles of the shunt and the current circuit of the dynamometer in addition to the usual compensation for differences in temperature coefficients. On the basis that it is desirable to eliminate cause for compensation wherever possible, it would appear that the use of a directly-connected current circuit was preferable.

The potential circuit of the dynamometer wattmeter with the usual external resistor is adapted for voltages up to about 150 volts, so that for measurements at higher voltage it becomes immediately necessary to arrange for properly applying the high voltage to the potential circuit of the dynamometer wattmeter in such a way that the power in the high-voltage circuit can be accurately determined. Though this same problem is solved simply and universally in general instrument practise today by means of instrument potential transformers[22], the application of these alone to measurements of dielectric power loss is not so satisfactory because of the phase-angle correction involved at the low power factor of the measurement[23].

In this connection Table I is of interest, for it shows the maximum allowable departure in phase angle from the true value for different percentage errors for different values of power factor. Since values of phase angle for instrument potential transformers are usually certified to as being correct within from 3 to 5 minutes, it is reasonable to assume that a departure in phase angle of at least 2 minutes from the true value may exist. For this condition it is seen that measurements to within an error of one per cent are not obtainable practically, to within five per cent are not obtainable for values of power factor 0.01 and less, and to within 10 per cent are not obtainable for values of power factor 0.005 and less. It follows, therefore, from the standpoint of phase angle alone that for the majority of these measurements the least error that can be reasonably expected will be in the order of 10 per cent.

TABLE I

Power Factor cos θ	θ	Maximum Allowable Departure in Phase Angle for an Error of					
		1%	5%	10%	25%	50%	100%
		Minutes					
0.002	89°53′	0	0.3	0.6	1.6	3.3	7
0.005	89°43′	0	1	2	4	9	17
0.01	89°26′	0	2	4	8	17	35
0.02	88°51′	0.5	4	8	17	35	70
0.03	88°17′	1	5	11			
0.05	87° 8′	2	8				
0.10	84°16′	4	19				

An additional correction must be made for the phase angle of the potential circuit of the dynamometer wattmeter. Unless the potential circuit is accurately shielded, the phase angle is difficult to calculate and may introduce an additional error in excess of those shown in Table I. For these reasons, the practise of correcting by calculation has been generally abandoned.

Use of the Air Capacitor Compensated Dynamometer Wattmeter Method

The errors resulting from calculating corrections and from those causes not readily susceptible to calculation can be almost entirely eliminated by the use of a high-voltage capacitor so designed as to have a negligible loss [12, 24, 25, 31], and across which the high voltage of the circuit may be directly impressed. Such a capacitor is usually one with air as a dielectric though capacitors with CO_2 gas under pressure have been used. If the loss in the capacitor is zero, then when the current circuit of the dynamometer wattmeter is connected into the capacitor circuit and voltage is impressed across the potential circuit of the wattmeter such as by instrument potential trans-

former, the dynamometer wattmeter should indicate zero assuming no loss in the current circuit. It probably will not do so because of the combined phase angle of the instrument potential transformer and the potential circuit of the dynamometer wattmeter, but it may be made to do so by changing the reactance of the potential circuit until such a result is obtained. The dynamometer wattmeter is thus correctly compensated for existing phase-angle differences. The capacitor may now be replaced with the cable sample of the same capacitance, and the resulting deflection read on the scale of the dynamometer wattmeter. The capacitor and the cable sample are connected to the circuit at all times. The power in watts is then directly calculated from the deflection and the watt-constant as obtained with direct current. This method is usually referred to as the Compensated Dyna-

mometer Wattmeter Method, and since first described by Shanklin[12] in 1916 has been found to give reliable results.[26] The circuit diagram for this method is shown in Fig. 3, in which diagram are shown the shields and ground connections necessary to be provided to eliminate errors due to electrostatic and electromagnetic induction.

By this method the manipulation and corrections are reduced to simple form. The dynamometer wattmeter can be calibrated in position at any time by

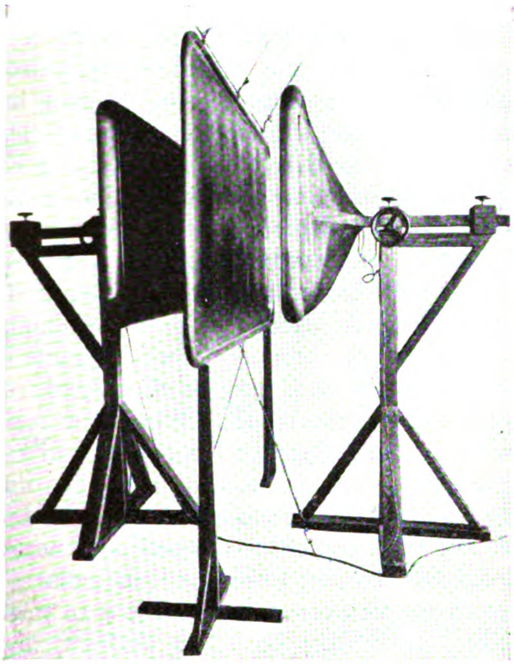

FIG. 4—AIR CAPACITOR. THREE-PLATE VARIABLE-CAPACITANCE TYPE

The middle plate is the high-voltage plate and is 9 ft. long and 5 ft. wide. The low-voltage plates are each 7 ½ ft. long and 3 ½ ft. wide. The capacitance range is from 0.0001 to 0.002 microfarad. The maximum voltage is 100 kv.

taking reversed readings on direct current, reading the values with a potentiometer. This assures accuracy of watt calibration. Losses in the current circuit can be calculated and corrected for if necessary. All phase-angle differences are corrected for by the compensation of the potential circuit.

The use of the air capacitor is quite prevalent in the art today and its use greatly facilitates measurements made with the dynamometer wattmeter. Two commercial forms of such capacitors are shown in Figs. 4 and 5, being of the variable and fixed-capacitance types, respectively. The suitability of any given capacitor of this type can be determined from a consideration of the design and from tests such as those described[12]. Though the loss is not absolutely zero, it is possible to determine its negligibility within satisfactory limits. A value of phase angle of 0.5 minute is considered possible of attainment, and the design must be such as to provide this attainment if the advantages of the method are to be realized. The error introduced by phase angle of the air capacitor is to make the final reading of power to be lower than the true value.

For best results the capacitance of the air capacitor should be equal to that of the sample being measured so that circuit conditions are maintained as nearly identical as possible during compensation and during measurements. Such a condition can be obtained without undue difficulty for 10-ft.-of-lead samples of present-day cables. For long factory lengths, however, this condition is practically prohibitive. It is therefore necessary either to compensate on a current coil of low-current rating and make the measurement on a current coil of high rating, or use a shunt. Either of these methods introduces corrections which may be uncertain. Bridge methods are apparently more susceptible to accurate results for such measurements as these[26].

The sensitivity of the dynamometer wattmeter varies with the design, and is in the order of from 10^{-4} to 10^{-5} watts per millimeter deflection at 110 volts when the scale is set at the conventional distance of one meter from the instrument. This is also the

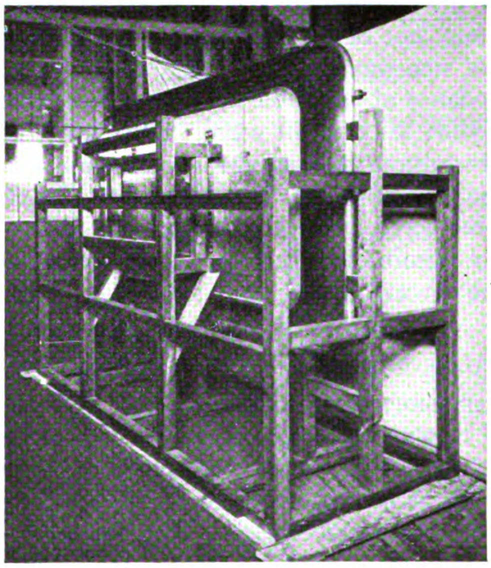

FIG. 5—AIR CAPACITOR. THREE-PLATE FIXED-CAPACITANCE TYPE

order of the lowest values of dielectric power loss to be measured (at the wattmeter terminals) in cable samples (10 ft. of lead) so that for such values the reading error alone may be in the order of 20 per cent since the deflection may be only a few millimeters accurately read to from 0.3 to 0.5 millimeter. For higher values of power the reading error expressed as a percentage value becomes proportionately less.

The choice of means of voltage transformation is pertinent. A set of instrument potential transformers for different voltage ranges is undoubtedly the best,

and these are commercially available up to 132 kilovolts. Ratio transformations obtained with these are independent of the current in the high-voltage circuit. The use of transformer voltmeter coil, though convenient, requires compensation for every measurement, since the transformation is affected by the current in the high-voltage circuit. The same applies to the practise of taking the potential from the low-voltage side of the testing transformer.

The effect of the earth's field is eliminated by making the dynamometer wattmeter astatic, although this is hardly necessary when measuring alternating power. Strong external alternating fields such as from high-current circuits or reactors nearby may, however, seriously affect the dynamometer wattmeter of the reflecting astatic type. Hence, it is quite essential to see that such external fields are eliminated when the dynamometer wattmeter is in use.

The dynamometer wattmeter accurately summates the power due to the like frequencies in voltage and current, and therefore should give the true power regardless of wave form. For cable testing, however, where the current circuit of the dynamometer wattmeter is in the cable circuit, and where the potential circuit of the dynamometer is supplied by means which may or may not be affected by the cable capacitance, the use of sine wave is highly desirable because of the low impedance of the cable to higher harmonics which act to distort the current wave. Also, from the standpoint of voltage measurement, the applied voltage should be of sine-wave form. The prevalence of the use of sine-wave generators today for cable testing is largely eliminating the need for worry regarding errors due to wave form[26].

Inductance Variation Method
Phase-Defect Compensation Method

Another somewhat similar application of the dynamometer wattmeter and air capacitor is used whereby with the capacitor in the circuit the dynamometer reading is brought to zero by means of inductance in the potential circuit. The cable sample of same capacitance is then substituted in the dynamometer wattmeter current circuit for the capacitor and the dynamometer reading is again brought to zero by means of the inductance in the potential circuit. From the change in inductance and the resistance of the potential circuit, the power factor is calculated.[2] This is frequently referred to as the inductance variation method, or the phase-defect compensation method.

Series Resistor and Wattmeter Method

A series resistor may be used with the dynamometer wattmeter in either of two ways. First, it may be used as a substitute for the transformer, the air capacitor still being retained for use in compensating the dynamometer wattmeter. In this case the conditions of use and possible results would be somewhat similar to those when the transformer is used. A series resistor has also been used instead of the transformer and air capacitor, connecting the resistor directly across the high-voltage circuit with the potential circuit of the wattmeter connected either in series with it, or in parallel with a portion of it. Such a resistor must be of fixed value, wherein the leakage to ground and the reactance are so extremely small as to be negligible. For the higher voltages such a resistor is necessarily large and quite expensive, and the problem of shielding is quite complicated. Barbagelata and Emanueli[17] speak of a suitable series resistor for such measurements as being costly and cumbersome, and state that it may have a phase-angle correction larger than those being measured.

The use of a water-column series resistor is being employed in these and similar measurements by some observers[17, 19]. As used by Barbagelata and Emanueli[17] the power factor of the cable insulation being measured is obtained by calculation from circuit constants, one of which is the resistance of the water column. A measurement of this value is therefore required under each condition of use, except at extremely high voltages such as 100 kv. and more, where, under certain conditions, the value of R may be eliminated from the equation expressing the result. Where the resistance of the water column changes frequently and requires frequent measurement as in most of the work in our country today, and where circuit constants enter into the calculation of the result, this method does not appear to be altogether without objection, particularly if the error due to capacitance of the resistor to ground is considerable, as it may be. The authors, however, describe a form of water-column resistor which is claimed to be free from capacitance error.

In this particular regard the work being done under the direction of Professor Ryan[19] in measuring corona losses at high voltages merits consideration, in that a method is given for shielding the water-column resistor and adjusting it to eliminate errors due to capacitance. This result is obtained by varying the resistance of the water-column resistor by varying the water flow and thus its temperature, the capacitance remaining constant. By taking readings of the wattmeter for different resistances, the shielding can be adjusted to give a zero error.

Some comparative measurements have been made with this method and with the compensated dynamometer wattmeter method the results of which are shown in Figs. 6, 7, 8 and 9. The dynamometer wattmeter with water-column resistor was set up as first described[19] by Clark and Miller although the instrument was connected into the ground side of the circuit and the pail was replaced with a continuous hose connection from the point of high potential down nearly to the drain. This hose was banded at intervals and the bands connected to similar bands on the resistor hose to distribute the potential properly. Under these conditions agreement was obtained with

measurements of power factor made with the compensated dynamometer method to within 0.004 on the cable sample, Figs. 6 and 7, and within 0.005 on the experimental capacitor, Figs. 8 and 9, except at the lowest voltage. These departures represent differences from the results obtained with a compensated dynamometer wattmeter method in the order of from 20 per cent to 80 per cent.

The later work as reported by Carrol[19] wherein a

method were used for measuring dielectric power losses in cable insulation. In making these tests the need for greater control of the resistance of the potential circuit was evident. Short-circuiting one turn of the water-column resistor was tried to obtain the desired range, but the resulting values obtained as shown in Figs. 8 and 9 show that error was introduced thereby.

While the use of the water-column resistor in measurements of dielectric power loss and power factor of

cables doubtless has merit and warrants further investigation, it does not appear to be inherently more accurate than the present established methods, such as the use of the instrument potential transformer and air capacitor.

Resonance Wattmeter Method

The resonance wattmeter method as early described by Rosa[1] and as used recently by Marbury[20] for measuring dielectric power losses and power factor in capacitors has merit, but would doubtless be some-

what difficult of application to cables because of the wide range of capacitance of samples of different rating and cables of different lengths. The accurate determination of the losses in the inductance to be subtracted from the wattmeter reading for the various conditions of measurement would entail the use of detailed equipment which would not simplify the measurements.

Measurement of Voltage and Current

In all of the above methods, the voltage and current must be measured, since the dielectric power loss is a function of the voltage and since the power factor is calculated from the value of dielectric power loss, applied voltage, and resulting current.

Values of voltage may be read with sufficient accuracy with a portable direct-reading voltmeter, the high voltage being transformed either by instrument potential transformer or by transformer-volt coil.

The current, usually of low value, is best read with a reflecting astatic dynamometer ammeter, which may be a separate instrument or may be the dynamometer wattmeter used for the measurement of dielectric power loss, connecting the potential circuit, with a suitable shunt, in series with the current circuit.

Measurements on Three-Conductor Cables

The discussion thus far has been confined to the dynamometer wattmeter itself and to its application in a single-phase circuit. The measurement of dielectric power loss and power factor of three-conductor cables presents more difficulties. In general, two methods are used at the present time (1) direct measurement from three-phase supply[14] and (2) calculation of the three-phase results from tests made from single-phase supply[13, 26].

Probably the simplest method suggested for making the dielectric power loss measurements from three-phase supply is to measure the power input to the transformers from the low-voltage side with the cable sample connected to the high-voltage side and then disconnected therefrom, the difference of these readings giving the value of dielectric power loss in the cable insulation. Unfortunately, the latter is too small to be accurately measured by this method except at the higher temperatures. Even under these conditions, the final result is the difference of two comparatively large values differing by only a small amount which is not highly accurate.

It thus becomes necessary to make the measurements on the high-voltage side. Although the principle of compensating the dynamometer wattmeter for circuit effects is still applicable, as in the single-phase circuit, it cannot be applied directly to each phase because the current circuit of the dynamometer wattmeter must be connected into the cable circuit between the grounded neutral point and the high-voltage winding of each transformer separately. Thus, the current due to capacitance to ground of the high-voltage winding, and between high-voltage and low-voltage windings, traverses the current coil of the dynamometer wattmeter but not the cable sample or the air capacitor. In a small transformer, error due to this cause may not be large. In a large transformer, shielding is absolutely necessary between the high-voltage and low-voltage winding. Fig. 10 shows the difference in power factor of a cable as measured with a shielded and an unshielded transformer of 100-kv-a. rating at 100 kv., the transformers being similar in other respects, the current coil of the dynamometer being connected between ground and the high-voltage winding. Other sources of error largely indeterminable are also present to varying degree, such as voltage unbalance and interphase effects which are not susceptible to correction, thus rendering the result somewhat uncertain.

Farmer[14] has described and used a method employing the dynamometer wattmeter in a three-phase circuit, later modifying the set-up to provide for compensation with an air capacitor, shifting the instrument from phase to phase, measuring both the dielectric power loss and the reactive volt amperes, the power factor being determined from the ratio of the two.

Note that measurements are at comparatively low voltage, and that differences are increasing considerably with voltage increase

• Unshielded transformer

○ Shielded transformer

The method of calculating the dielectric power loss from measurements made from single-phase supply[13, 26] has the advantage of employing the simpler single-phase measurement which is subject to greater accuracy and certainty in final result. It has the disadvantage of the uncertainty of the calculations embodying the resulting phenomena in the cable exactly. Check measurements between those made from three-phase supply and single-phase supply in general show good agreement, neither method giving consistently

lower or high values. Farmer[14] states that the measured value is frequently considerably lower than the calculated value. Figs. 11 and 12 show comparative results in this regard, obtained in two different laboratories on two different samples of cables cut from the same length. Agreement of power-factor values is within from 0.002 to 0.004. The per cent of difference from the mean is 20 per cent over the entire range of values. Figs. 13 and 14 show results of similar measurements made on the same sample of cable in the same two laboratories. Agreement of power-factor values is within 0.002. The maximum per cent difference from the mean is 20 per cent; remaining values show closer agreement, and at some points actual agreement. On the assumption that the different methods give values subject to approximately the same errors, these results indicate the departure from the true result for both methods to be in the order of from 10 to 20 per cent.

ACCURACY OF MEASUREMENT

In the absence of known means for definite comparison, the accuracy of these measurements must be determined in other ways. Comparison of measurements made by independent methods is helpful.

It has been shown[26] that for single-conductor cables measured by compensated dynamometer wattmeter method, and by Schering Bridge method that agreement in power factor has been obtained within 0.002. This is at a value of power factor in the order of 0.005, thus the resulting departure from the average value by the two methods is about 20 per cent. Note that the percentage error may seem somewhat high, but this is characteristic of this means of expression where the base values are small. However, the agreement in absolute value is very good.

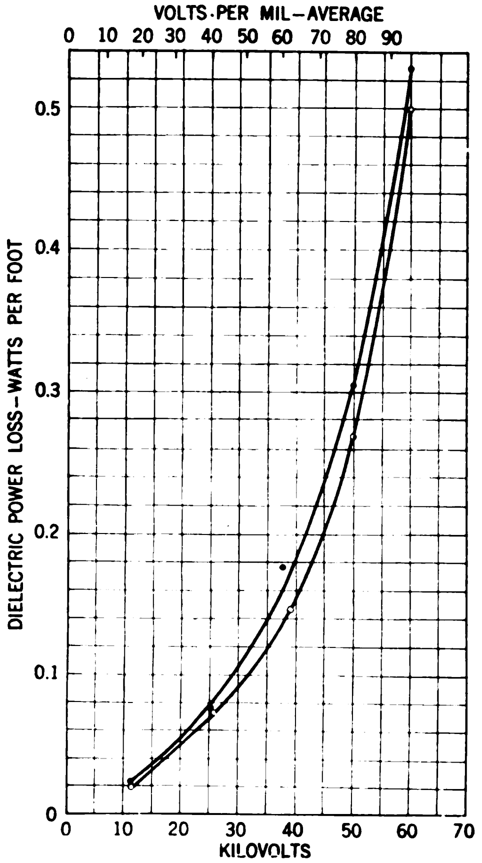

Fig. 15—Comparative Measurements in Two Different Laboratories of Dielectric Power Loss in the Same Cable Sample—Cable Rated Single-Conductor. 500,000-cm., Round, 5/8-In. Treated-Paper Insulation, Lead-Covered

• Laboratory A. Compensated dynamometer wattmeter method
O Laboratory B. Phase-defect compensation dynamometer wattmeter method

Figs. 15 and 16 show results of measurements made on the same sample of single-conductor cable in two different laboratories using the compensated dynamometer wattmeter method and the inductance variation dynamometer wattmeter method (phase-defect compensation method) respectively. Agreement is within 0.02 watt in 0.1 watt for dielectric power loss, and within a power factor of 0.001 at a value of power factor in the order of 0.005. This indicates departure from the average value for the two measurements to be in the order of 10 per cent. The curves of Figs. 11 to 14 show similar results for two methods of measuring three-conductor cables where the departure from the average value for the two methods is in the order of from 10 to 20 per cent.

Conclusion

An appeal has been made for greater attention to the question of making these measurements, large differences—as much as 100 per cent—on a percentage basis having been reported.[30] The discussion given above shows that these measurements are now being regularly made with dynamometer wattmeter methods giving results wherein the probable departure from the true value is within from 10 to 20 per cent in percentage value. Such results are not obtainable with ease, but only after intense application and using available intercomparisons as a means of eliminating possible unknown errors.

In this regard a usable means of definite comparison is quite desirable. Much thought has been placed on

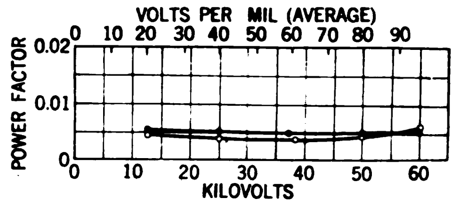

Fig. 16—Comparative Measurements in Two Different Laboratories of Power Factor of the Same Cable Sample—Same Cable as in Fig. 15

• Laboratory A. Compensated dynamometer wattmeter method
O Laboratory B. Phase-defect compensation dynamometer wattmeter method

procuring a suitable comparator which could be used for standardizing any measuring outfit for dielectric power loss and power factor. No satisfactory means has yet been made applicable.

As far as the author knows no attention has been paid to the calorimeter method as being useful for such a comparator. Such a method was used early in the the art in connection with measurements on capacitors and has since been successfully applied with satisfying results. Though the difficulties of such a measurement with cable samples are more severe than with capacitors, nevertheless it is felt that there is a field for such a measurement and for which definite specifications could be drawn up as a comparator, which would enable different measuring equipments to be adequately standardized. The possibilities of development work in this regard are quite worth the effort.

THE EFFECT OF GOOD LIGHT

The effect of good light on factory output was demonstrated last winter in a ball-bearing plant. Without the knowledge of the workmen, illumination was raised from five-ft. candles to 20-ft. candles. Production increased 12.5 per cent. Lighting cost per hour in that section of the factory under test was increased 28 cents and the hourly saving to the company through increased production was $1.47.

Circulation of Harmonics in Transformer Circuits

BY T. C. LENNOX[1]

Associate, A. I. E. E.

Synopsis.—The paper describes the manner in which certain series of harmonic currents may be permitted to flow within a transformer network. In particular it is shown how the fifth and seventh harmonics of transformer exciting current may be eliminated from transmission lines. The extent to which the harmonic currents generated in a rectifier may be eliminated from the a-c. lines by means of phase multiplication is also indicated.

* * * * *

THE action of a third harmonic of current or voltage in three-phase a-c. transformers has become familiar to engineers. Very exhaustive studies of the third harmonic of transformer magnetizing current, in particular, have been necessary, due to the excessive voltages that may result in Y-connected, three-phase circuits where the harmonic of current cannot flow, and to excessive interference with telephone circuits when it flows in a grounded neutral circuit.

It has not been so generally appreciated that this is but one of many similar phenomena that may be encountered if other harmonics than the third and other connections than the simple three-phase, Y, or delta are studied.

The case of the third harmonic of magnetizing current in three-phase transformer circuits is reviewed briefly. Here, it is usual to have three transformers or phases of similar characteristics so that the wave form of the magnetizing current is the same in each phase. Consequently, the third harmonic of current will be the same magnitude in each phase and have the same relation to the fundamental wave.

Bearing this in mind, we may take the case of a three-phase bank, connected in delta on one side and with excitation applied to this winding. Examining, then, the condition at one corner of the delta, it is found that the fundamental waves of exciting current of the two phases differ in phase by 60 deg. The third harmonics of current having three times the frequency of their fundamentals will differ in phase by three times 60 deg., or 180 deg. In other words, they will be equal and opposite and no third harmonic of current will flow from the supply circuit.

Next considering the Y connection, it is found that whereas at the neutral the fundamental waves are 120 deg. apart in phase, and consequently add up algebraically to zero, the third harmonics are three times 120 deg., or 360 deg. apart; or, in other words, are all in the same phase position and consequently add up to three times their average value and must flow into the neutral line. If no neutral is provided, no third harmonic of current can flow and consequently a third harmonic of voltage will appear from line to neutral in each phase.

The exciting current of a transformer contains higher odd harmonics,—the fifth, in particular, being quite prominent although smaller than the third. The seventh and some higher harmonics, although present, are of negligible amount. Considering these harmonics at a corner of the delta, the fifth harmonics will differ in phase five times 60 deg., or 300 deg. and will consequently have a resultant 1.73 times their average value, which must flow in the supply line. Similarly the seventh harmonics differ in phase 420 deg. or, subtracting 360 deg., 60 deg. and have a resultant in the line 1.73 times their average value. Similarly, the eleventh, thirteenth, and other odd harmonics not multiples of three must flow in the line, whereas the ninth, fifteenth, and others which are multiples of three, will equalize in the same manner as the third.

At the neutral of a Y connection, the fifth harmonics will differ in phase five times 120 = 600 deg. or 240 deg., and consequently will add up to zero the same as the fundamental. Similarly the seventh, eleventh, and other odd harmonics, not multiples of three, will equalize and may, therefore, flow in such a circuit without a neutral line. On the other hand, the ninth, fifteenth, and other harmonics which are multiples of three cannot flow.

Consider next the case of a Y-connected bank placed in multiple with a delta-connected bank, Fig. 1, in which all the phases are identical in characteristics, being different only in the turn ratio as necessary to obtain Y or delta connection. At each corner of the delta, three currents converge, so that the fundamental waves add to a resultant of twice the value of that in the Y-connected phase and in phase with it.

The third harmonic cannot flow in the Y connection and will equalize to zero between the two phases of the delta. A third harmonic of voltage exists from line to neutral in the Y-connected units, but if they have delta-connected, secondary windings, the voltage will result in a triple-frequency current in the delta which will reduce the voltage to a practically negligible value dependent on the impedance of the windings.

As the fifth harmonic can flow in the Y connection, there will be a fifth harmonic in each of the three phases converging at the corner of the delta. The delta phases being 30 deg. each way from the Y phase, their fifth harmonics will be 150 deg. out of phase with the fifth in the Y phase. This will result in the three adding up to zero with no fifth harmonic flowing in the line. Similarly with the seventh harmonic, the 30 deg. is multiplied to 210 deg. and the three equalized to zero. The ninth will act similarly to the third, flowing in the delta, and in the secondary delta of the Y-connected phases.

1. Transformer Engineering Department, General Electric Company, Pittsfield, Mass.

Presented at the Regional Meeting of District No. 1 of the A. I. E. E., Niagara Falls, N. Y., May 26-28, 1926.

For the eleventh harmonic, the 30 deg. becomes 330 deg. and the three phases have a relation identical with that applying to the fundamental, so that the full value of the eleventh harmonic must flow in the line. Similarly for the thirteenth harmonic the 30 deg. becomes 390 deg. and the full value of this harmonic must flow in the line.

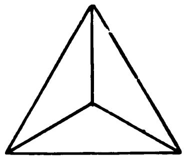

Fig. 1

Continuing the process, we find that all the odd harmonics except the eleventh, thirteenth, twenty-third, twenty-fifth, thirty-fifth, thirty-seventh, and others of that series will equalize within the network.

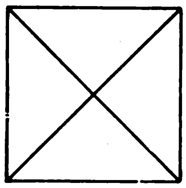

Fig. 2

This is of some practical interest in connection with power transformers or shunt reactors in cases where the fifth harmonic of exciting current may be thought to have some bearing on telephonic interferences.

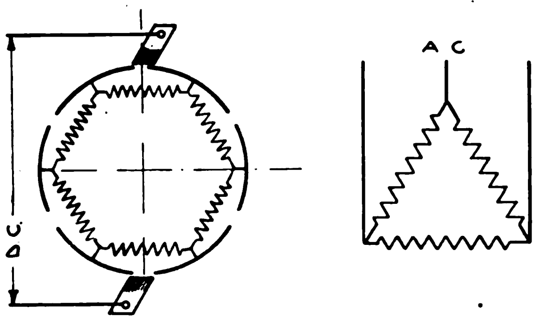

Fig. 3

By suitably arranging the banks so as to balance delta banks against Y banks, the fifth and seventh harmonics of exciting current may be largely eliminated from the lines.

If an analogous connection on a quarter-phase system consisting of a cross-square connection is taken, as in Fig. 2, it is found that the harmonics of the series 3, 5, 11, 13, 19, 21, 27, 29, etc., are equalized while those of the series 7, 9, 15, 17, 23, 25, etc., must flow in the line. A secondary square in the cross bank is not needed unless it is wished to eliminate even harmonics, in which case the second, sixth, tenth, and so on would flow in the squares.

An interesting case in this connection is a polyphase rectifier circuit such as is suitable for use for changing alternating current to direct current. Such a rectifier tends to draw current from the a-c. system having a wave form approximating the rectangular in shape. This wave consists of a series of odd harmonics the magnitude of which is in inverse ratio to their order, that is, in the familiar Fourier series.

Considering a six-phase ring, Fig. 3, with commutator and brushes or their equivalent arranged to operate in synchronism with the alternating voltage, the current in the ring will approximate the form shown in Fig. 4.

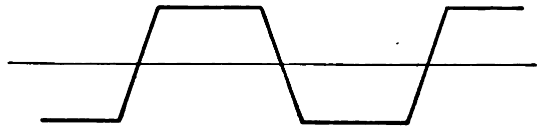

Fig. 4

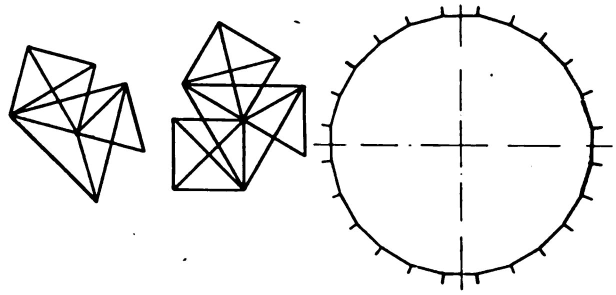

Fig. 5

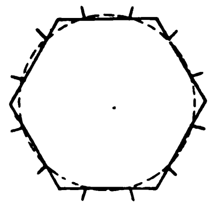

Fig. 6

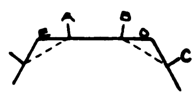

Fig. 7

The current in each phase has to reverse while the phase is short-circuited by the brush. This requires a definite time and explains the slanted sides in place of the vertical sides of a rectangular wave. A series of odd harmonics somewhat similar to that in a rectangular wave will, nevertheless, be present. If the primary of the transformer is connected in delta, the third and other harmonics which are multiples of three will equalize at the corners and the line current will consequently have only the fundamental and the remaining harmonics.

If the number of sides in the polygon is increased to eight by the use of four separate transformers or phases with the necessary number of windings for this arrangement and the primaries are connected cross-square (Fig. 2), the harmonics of the series 3, 5, 11, 13, 19, 21, etc., are eliminated, leaving the remaining ones in the line.

If a twelve-sided polygon is used by means of six single-phase transformers or two three-phase transformers and Y-delta primaries are used with additional delta in the Y phases, all the harmonics except the 11th, 13th, 23d, 25th, and others of that series are eliminated.

For a still larger number of phases in a polygon obtained by the use of separate transformers or core legs, we cannot obtain a simple primary connection of the kind used above. However, for 24 phases using either 12 single-phase or four three-phase transformers, a set of compensating windings placed on the same cores as shown in Fig. 5 could be connected. Here, we have the necessary Y deltas and cross squares to carry all the harmonics except the 23d, 25th, 47th, 49th, 73d, 75th, and others of that series. The three-phase, a-c. connection to such an outfit would be made at any three points equally spaced around the polygon. In any of these polygons, it is possible to double the number of symmetrical phases by tapping out the leads as shown in Fig. 6, so as to have all the connection points fall on a circle intersecting the polygon at equal intervals. Here, the primary or compensating winding will eliminate only the same series of harmonics as for the smaller number of phases. However, some of the remaining harmonics are cancelled within the polygon

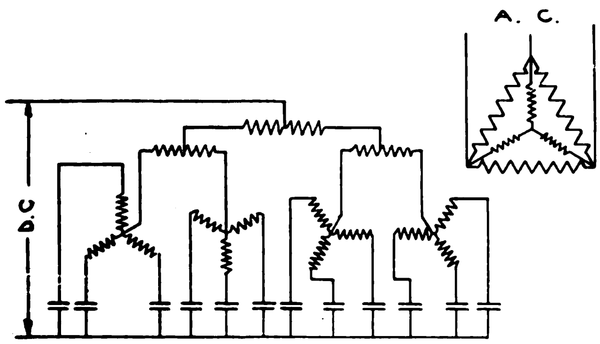

Fig. 8

itself, as for instance, in Fig. 7 which shows a part of a 12-phase connection from a six-phase ring. The current in *B C* is 150 deg. from that in *B A* but flows in coils *B D* on the same core. The fifth harmonic will be 750 deg. or 30 deg. from that in *B A* and, together with that in *A E*, will have a resultant equal and opposite to the fifth in *A B*. Similarly the seventh harmonics will be 330 deg. out of phase and will neutralize.

As a result, no current of these frequencies will be required of the primary coils or line and the residue of harmonics to be taken from the line will be the same as for a polygon having the full number of separate phases.

Table I shows the magnitude of the minimum residue of odd harmonics for polygons of different numbers of phases, in per cent of the fundamental, for a rectangular wave in the polygon. From this it is evident that the minimum ripple resulting in the a-c. lines in such cases is composed of a series of odd harmonics comprising the numbers adjacent to the number of phases in the polygon and its multiples.

The extent to which this ideal condition may be approximated in the case of actual designs will depend principally upon the reactance of the circuits through which the harmonic currents are required to flow. In the arrangements outlined above the primary windings or compensating windings if used, must have small leakage reactance between them and the polygon if more than a few of the lower harmonics are to flow in appreciable amount.

Transformers for tube rectification are frequently connected in star rather than in a polygon. If there are

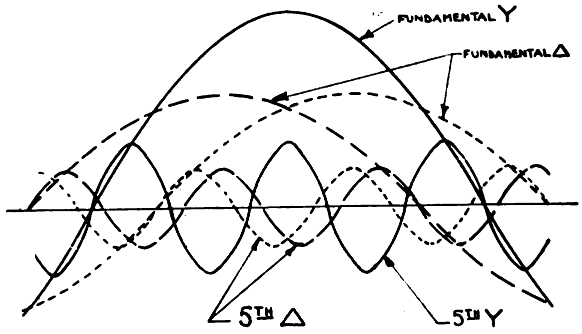

Fig. 9

an even number of phases with this arrangement all even harmonics will cancel. A series of odd harmonics will remain as in the polygon connection and will be eliminated in the same manner and to the same extent. The use of separate Y-connected banks, connected together by inter-phase transformers, as shown in Fig. 8, will not greatly alter the conditions, the minimum residue of harmonics from the 12-phase system shown being the 11th, 13th, 23d, 25th, etc., series. The wave forms to be expected in tube rectifiers are described in some detail by D. C. Prince, in the General Electric *Review* of September, 1924.

To illustrate more clearly the action of the harmonic currents, Fig. 9 shows the fundamental and fifth harmonics at the corner of a Y-delta connection when the harmonic is in phase with the fundamental at its crest.

The Cosmic Harness of Moving Electricity
President's Address

BY M. I. PUPIN

Fellow, A. I. E. E.

Moving Electricity the Mother of Electrical Engineering

The Annual Convention brings us together for the purpose of advancing our knowledge of each other and of the ideals of our Society. We believe that our ideals are in harmony with the ideals of American science and American engineering, and, moreover, we believe that we have a place of honor among those whose mission is the cultivation and amplification of these ideals. They furnished the motive power for the rapid advancement of the science and the art of electrical engineering during the last hundred years. The advancement has been very rapid, but, nevertheless, no other art has a scientific foundation which is so deep, so broad, and so firm as the foundation of electrical engineering. In no other department of human knowledge are science and art so closely welded together. These statements, I know, many will consider as somewhat too bold. I shall try to justify them by referring briefly to the outstanding events in the history of the art of electrical engineering and of the science to which it is welded.

The very meaning of the word engineering implies an art which guides the activities of physical forces into channels of useful service. When the Galileo-Newton philosophy had disclosed the laws of motion of terrestrial as well as of celestial bodies, a new universe was revealed to man, a universe of orderly motion of matter in obedience to forces acting in accordance with laws of child-like simplicity. This philosophy suggested to the engineer new sources of power and service, and to the natural philosopher a new and apparently most comprehensive view of physical phenomena. Some philosophers, thrilled by the beauty of the new knowledge, believed that the whole future history of the universe could be foretold by the Galileo-Newton philosophy if we only knew at any given moment the configuration, the state of motion of every one of its parts and of the forces acting between these parts. That was the mechanistic view of the universe which flourished soon after the triumph of Newton's great achievements. These achievements, however, misled some enthusiasts into the belief that all physical phenomena are reducible to orderly motions of matter under the action of gravitational forces. But as soon as man had discovered that other processes, not expressible in terms of motion of matter, formed an essential part of physical phenomena, that belief was abandoned.

Among these processes, the motion of electricity stands foremost. The new universe revealed by our knowledge of the motions of electricity appeals to our imagination so strongly today that many would not hesitate to rewrite the first sentence of the book of Genesis as follows: "In the beginning God said, 'Let electricity move, and the embryo of the Universe began to form.'" Perhaps in a hundred years from now such a glorification of the motion of electricity will appear just as extravagant as the old mechanistic view of the universe. There is no doubt, however, that the nineteenth, and the first quarter of the twentieth century, will long be remembered as the epoch which revealed to us the hidden powers of electrical motions and their exalted position in our present knowledge of the universe. Who could have foretold all this when Stephen Gray, less than two hundred years ago, modestly announced that electricity can move any distance over conductors and that it does move with enormous rapidity? The world paid small attention to Gray's great discovery, and it might have continued its indifference if Franklin, instructed by his Leyden jar discharges, had not inferred that lightning is a motion of electricity. Gray's modest terrestrial experiment received from Franklin a celestial illustration which commanded attention, although it was ridiculed by some learned members of the Royal Society. The motion of electricity which, in Gray's experiment, was detected by a tiny electroscope assumed a sublime aspect when its flash in the heavens blinded the eye, deafened the ear, and shattered many stable structures of man.

Franklin's discovery of the electrical character of lightning was a great stimulus to the study of the motion of electricity. One may compare it to the stimulus which the Copernicus-Kepler revelation concerning the motion of the planets gave to the study of the motions of terrestrial bodies which Galileo inaugurated. Just as Copernicus and Kepler gave us a Galileo and a Newton, so Gray and Franklin were destined to be succeeded by an Oersted and a Faraday. But it required a Volta to introduce Oersted; it required large electrical motions to reveal the magnetic forces of moving electricity which Oersted discovered.

Prior to Oersted, the engineer moved material bodies and guided their motions into channels of useful service by providing a material connection between the driving and the driven body. Oersted showed that a material body which is the seat of electrical motions can make other bodies move without a material connection between them. The magnetic flux is the invisible coupling. Oersted's discovery of the magnetic field which accompanies electrical motions promised, therefore, to give birth to a new type of engineering, employing a new type of coupling. This promise was

Delivered at the Annual Convention of the A. I. E. E., White Sulphur Springs, W. Va., June 22, 1926.

one of the great incentives to the advancement of the new knowledge. The mechanical action of an electrically charged body upon other bodies gave a similar promise, but it failed, and it was destined to fail to make that promise good. The promise of the Oersted discovery blossomed out into a reality more beautiful than the fairest dream which prompted that promise. Electricity in motion offered to the engineer a moving force which proved much more powerful than that offered by electricity at rest. The lifting power of Henry's electromagnets was immeasurably greater than the lifting power of the gravitational action of the material out of which his electromagnets were made. One can imagine today what an impression that new fact must have made upon the mind of the engineer of a hundred years ago. Today one can say that electrical engineering is the science and the art which tell us how to make material bodies move by employing an invisible harness hitching up these bodies to moving electricity. It was born when Oersted made his discovery, but its growth was destined to be slow as long as the Voltaic battery was the only powerful means of generating and sustaining electrical motions. To Faraday belongs the glory of discovering a new and much more powerful instrument than the Voltaic battery. It was his clear vision which prophesied a reciprocal relation between moving electricity and moving magnetism. The prophesy was probably the offspring of the intuition which suggested that since moving electricity moves magnets, it is reasonable to expect that moving magnets will move electricity. This expectation proved correct, and it offered to the engineer an ideally simple and powerful method of setting electricity in motion. The promise of Oersted's discovery to the engineer assumed a new meaning after Faraday's discovery, and electrical engineering began its career which placed it in the exalted position it has today among the engineering sciences. The efforts of the electrical engineer to render useful service by hitching up material bodies to moving electricity resulted in the creation of the dynamo, the motor, the transformer, the telegraph, the telephone, and other epoch-making devices which have revolutionized the material conditions of human life. Grateful mankind responded with a generous support of the science which gave birth to and nursed the young art of electrical engineering and, like a wise mother, gave it its exalted ideals. These ideals are the bond of union between electrical engineering of today and its trusty guide, the electrical science. The progress of one brings quickly an equal progress of the other, because hand in hand they always walk together with equal step. One cannot contemplate their stately walk without recalling to mind the well-known line from one of the odes of Horace:

"O matre pulchra, filia pulchrior!".

The Harness of Moving Electricity

The enormous lifting power of electromagnets was the great scientific sensation of a hundred years ago. It excited the lively imagination of Joseph Henry, at that time a young engineer, and he was the first to give it a novel service when he designed the first electromagnetic telegraph which gave the first real job to the electrical engineer of a hundred years ago. The enormous lifting power of the electromagnet furnished also a new job to the natural philosopher when it forced upon him the question: What is the invisible coupling through which this force is transmitted from the stationary to the movable part of the electromagnet? Faraday was the first to suggest an answer to this question. His discoveries and visions detected what one may call an invisible electromagnetic harness to which all material bodies in the universe are attached and which is always available to be employed by moving electricity in useful service. Faraday and Maxwell taught us that this harness is woven out of the electrical and magnetic tubes of force. Change the electrical elements of this cosmic harness in any part of space and its magnetic elements will also be changed in accordance with Maxwell's extension of Ampère's law. Change its magnetic elements and its electrical elements will be changed in accordance with Maxwell's extension of Faraday's law of electromagnetic induction. It is by these changes that an action is transmitted from one part of free space to another. A more complete and, at the same time, ideally simple description of the operation of the invisible harness than that given by Maxwell was unthinkable sixty-one years ago. It became the foundation of the electrical science as well as of the electrical art, that is, of electrical engineering; it welded the two to each other. Faraday and Maxwell performed the welding process. Their mode of thought appealed to the engineer because it expressed the motion of energy from one part of space to another in terms of the action of the invisible coupling between them, furnished by the tubes of force. No elaborate mathematical process was required to aid our understanding of this action and yet the Faraday-Maxwell electromagnetic theory was often accused of being too mathematical, because its fundamental laws, mentioned above, when expressed mathematically were called Maxwell's equations. This conveyed the idea that the theory is a mathematical apparatus which cannot be operated by the mathematical skill of an ordinary electrical engineer and therefore of no use to him. Nothing can be more erroneous than this notion. Nothing is more concrete and simple than the Faraday-Maxwell electric and magnetic flux and nothing is more extensively used by the electrical engineer than these fluxes and the simple laws which govern their activity. No elaborate mathematical apparatus is necessary in order to understand that the Faraday-Maxwell science revealed to us the most accurate understanding of not only the mode of operation of the invisible coupling in ordinary electrical power generation and transmission, but also in the transmission of radiant energy from the distant stars to our terrestrial globe.

This understanding gave us the first glimpse of that unity of the universe in which the invisible harness, joining every one of its parts to every other part, is always ready to transmit service which moving electricity makes available.

Faraday and Maxwell, however, had not spoken the last word concerning the invisible cosmic coupling. New explorers of the boundless region, revealed by the visions of Faraday and Maxwell, have delivered and are still delivering new messages from this region, unfolding many of its secrets. What are these secrets and how does their unfolding affect the views of the electrical science and its art, electrical engineering?

Franklin was the first to profess the belief that all electricity has its origin in material bodies. Faraday's discovery, that to each atomic valency there is attached a definite electrical charge, gave Franklin's belief a more intelligible form, which appealed to our imagination more and more as the conviction grew stronger, that all chemical reactions are due to the activities of the atomic charges. It was this conviction which suggested the name "electron" to the smallest unit of atomic charges long before its independent individual existence had been demonstrated by actual experiment. Roentgen's discovery of the X-ray suggested the hypothesis that these rays are excited by the impact upon the anode of tiny projectiles, shot forth with enormous velocities from the cathode of a high vacuum tube. Experiment proved that these projectiles are the individual electrons, the existence of which in the atomic structure had been suggested by Faraday's electrochemical discoveries; experiment also determined their electrical charge and inertia. This is the foundation of modern *electron-physics* and it is so broad that it furnishes new support to the foundation of the Faraday-Maxwell electromagnetic theory, to chemistry, astrophysics, meterology, biology, and, above all, to electrical engineering. It has created a new electrical industry and a new type of electrical engineering. It is the busy electron in the amplifying vacuum tube which gives life to the radio broadcasting industry and supplies new problems to the electrical engineer, the so-called radio engineer; it carried conviction to those who were inclined to think that the tiny electron was only a fiction of a supersensitive scientific imagination.

The Electron, the Primordial Unit of Power Generation

The marvelous success of this new electrical industry and of the electrical engineering which guides it, directed our attention to the function of the electron in all electrical power operations. The result is that today the electron and its positive partner, the proton, have become the fundamental concepts in the science of modern physics and in the art of electrical engineering. The tubes of electrical force between them are the primordial electrical flux, the fundamental and the only substance in the web of the cosmic harness. The relative motion of that primordial flux manifests itself as the magnetic flux which measures the momentum of this relative motion. Relative to what? Relative to the observer who is measuring that momentum. A charge moving with the observer has no momentum relative to the observer and is not accompanied by a magnetic field which the observer can detect.

Electron-physics made a fundamental contribution to the achievements of Oersted, Faraday and Maxwell when it demonstrated the individual existance of the electron and the proton and pointed out that the electrical flux, which unites the two, is the primordial flux, the cosmic bond of union between all electronic granules in the universe. This is the invisible harness to which all parts of the cosmic space are hitched up. To the electrical engineer who is a disciple of the Faraday school of thought the electronic granules are unintelligible except as local convergencies of the primordial flux. It is the activity of the flux which tells him the story of energy movement from one part of space to another and without this energy transference, the motion of the isolated electronic granules would have but a very small interest for him. He is, it is true, interested in the cosmic processes by which heavier atoms are evolved out of lighter atoms by a suitable grouping of the electronic granules, but that which interests him incomparably more is the energy liberation in these processes and the invisible harness along which the liberated energy is transmitted, destined to perform some useful service in some distant part of space. He is also interested in the energy which is stored up in the formation of the atomic nucleus, and how much of it can be made available when the structure of the nucleus is changed as in radioactivity.

Electron-Physics interpreted in terms of Faraday's visions and Maxwell's quantitative formulation of them suggests to the electrical engineer a universe which reminds him of a power distribution system in which there are an endless number of power stations all interconnected by the primordial flux. Material bodies, from the smallest atoms to the biggest stars, are, according to this picture of the universe, local aggregations of electronic centers in the all-embracing, primordial flux. This cosmic structure, however, is not a static but a dynamic one. Every one of its electronic centers is in a state of activity, receiving energy from its busy neighbors and giving it out without cessation or rest. It is pulled by or is pulling at the cosmic harness to which it is inseparably attached. It is doing its share of service in the evolving universe, and how much of this service is to benefit man depends upon the man himself; upon his science and art of electrical engineering. It is the problem of the electrical engineer to transform the activity of the infinitely numerous, but infinitely small, electronic toilers in the cosmic power stations into orderly service for the uplift of the life of man. He is the coordinator of the restless activity of

these toilers; they follow his bidding as if guided by the magic wand which Faraday and Maxwell and their disciples gave him; they are his obedient servants. Here, they heat an electrical furnace and there, they guide chemical reactions; here they drive the propellers of a battleship, and there they turn the busy wheels of an industrial plant; here, they speedily carry the weary industrial toiler to his home and there, they make it cozy and comfortable by their light-giving service; here, they record the cheerless figures of the stock exchange ticker and there, they carry sweet melodies and soul stirring language to the millions of eager listeners on this hopeful continent.

It is a master mind, indeed, that can thus control the activity of an infinitely numerous army of toilers. No vulgar rule of the thumb can find a lasting place in the logic of such a mind; its art, is an exact science and its science is supported by an art the experience of which, through many generations, has been tested by methods of measurement of astronomical precision. No vague and hazy notions obscure the lucidity of the electrical engineer's operations. The enormous electrical efforts of his million-kilowatt power station are just as lucid to him as the feeble efforts of the tiny electrical power which brings us the wireless message from distant Australia. Both of these efforts are huge in comparison with the efforts of a single electronic toiler in terms of which the electrical engineer can express every electrical effort. He knows the numerical value of the labor of these tiny workers and he also knows that it is their toil by which the lily, without toiling or spinning, arrays itself in beauty which far surpasses Solomon in all his glory. It is their toil which promises to the civilization of man a beauty and glory which will far surpass the beauty of the lily. The mission of the electrical engineer is to make this promise good. In the performance of this mission, he will keep always in mind the words of St. Luke who glorified the blessedness of the indolent lily. The apostle said:

"And seek not ye what ye shall eat, or what ye shall drink, neither be ye of doubtful mind."

"But rather seek ye the kingdom of God; and all these things shall be added unto you."

The men who made the science and the art of electrical engineering did not seek what they should eat or drink. But in their thirst and hunger for the eternal truth they did seek and find, in part at least, the kingdom of God, which resides in the beauty of their science and its art, and in the beauty of the universe which they reveal. That science and its art are the creation of a new philosophy which we call the philosophy of idealism in science. It is the simplest philosophy ever constructed by the mind of man and represents the essence of scientific experience of centuries; an experience which was always guided by a definite motive, a definite mental attitude, and a definite method of work. The motive was the unselfish longing for God's eternal truth; the mental attitude always demanded an open minded and unprejudiced interpretation of nature's language; the method of work is that by which our patron saints Gray, Franklin, Volta, Oersted, Ampère, Faraday, Maxwell, Roentgen and their disciples created the science and the art of electrical engineering. This motive, mental attitude, and method of work is the firmest foundation of the scientific idealism which is the idealism of our profession and we have always been the leaders in the propagation of its gospel. We were the earliest apostles who converted the American industries, so that today they worship at the altar of the Idealism of Science. We must impress that idealism upon all phases of our national life, in order to assist our nation in the solution of the many complex problems of modern democracy.

OIL ENGINES RECLAIM THE DESERT

In the waterless desert, where natural power does not exist, oil engines are developing profitable industry by generating accessible power. A striking example of this may be found at Gerlach, Nevada. Here, in the granite mountains, a rich deposit of rock gypsum was discovered. It was ten miles from the nearest railroad and, being in the heart of the desert, coal was not obtainable. There was neither power, nor water, and there were no housing facilities. Added to these obstacles, the climate in the region covers an unusually wide range of temperature—from as low as 40 deg. below zero in winter to 115 deg. in summer.

The corporation quarrying the gypsum to make plaster of various kinds has overcome all these difficulties. A great mill has been erected and is running full blast, a five-mile aerial conveyor has been provided, a plant railroad has been built, an attractive village for the workmen has been constructed, and also, a large power house from which emanates electric power for manifold purposes. Where once the desert lay silent and untouched, engineering skill has created a busy hive of production—manufacturing one of the greatest industrial necessities, plaster. The machinery about the mill is driven by electric motors, the power being generated by three 8-cylinder 800-h. p. engines, each connected to an electric generator. Owing to the climate, special open-air construction was used to facilitate the radiation of heat from the conductors. These 800-h. p. engines use heavy fuel oil and employ the same principles of fuel injection as the engines used in the oil-electric locomotives which are attracting so much attention from railroad executives on account of their economical fuel consumption. Oil engines such as these, utilizing a minimum amount of precious water, are an available asset in the Nevada desert. The same economy in water applies also to the oil-electric locomotives.

Marine Work

Annual Report of Committee on Application to Marine Work*

L. C. BROOKS, Chairman

To the Board of Directors:

The work of the Committee on Application to Marine Work for this year has been very largely a continuation of the work of the last year, in connection with the compiling of the Revised Rules, which we hope will be ready for publication during the present summer.

As has been the case in the past several years, the work of this committee has been divided into sections, each in charge of a subcommittee, including propulsion, power apparatus, interior communication, fixtures and fittings, wire and cable, radio, historical, and editing. Each subcommittee prepared revisions of the Marine Rules applicable to their work, which revisions were discussed and approved by the main committee, and afterwards turned over to the editing committee for final compiling.

The work of these subcommittees is to be commended, especially from the fact that there are many avenues of thought which needed to be correlated into a unified final decision by the main committee. The entire revision is now in the hands of the editing committee, and it is anticipated that it will be ready for publication very shortly.

At the present time the marine industry is not active, of course, but due to the fact of more stringent requirements of insurance, it is very important that these Revised Rules may be issued as soon as practicable, in order that the United States may have some definite standard as a basis.

A. I. E. E. Marine Rules are now accepted as standard, as far as applicable, by the American Bureau of Shipping, and nearly all of the naval architects and shipbuilding companies.

In addition to the work on the Marine Rules as above mentioned, there were several committees consisting of other lines of thought that were allied with the marine work, as follows:

Personnel Committee, working in conjunction with the Department of Commerce and new commanding officer in charge of the steamboat inspection service; also working in conjunction with the law officer of the Shipping Board. There is considerable optimism that some definite results will be obtained in connection with the proper recognition of electrical engineers on board ships.

This committee has also given assistance in connection with the Department of Commerce, which is endeavoring to establish a uniform practise in fire alarm laws, which is a very important subject in connection with marine navigation. This phase of the question will include also electrical systems or devices in the form of automatic steering arrangements, navigating instruments, sounding machines, etc.

In connection with the committee as a whole, it is with regret that we chronicle the death of W. F. Meschenmoser of the Russell & Stoll Company. Mr. Meschenmoser has been for many years an active member of this committee and chairman of the subcommittee on fixtures and fittings; his work will be greatly missed in future activities and meetings of this committee.

Also, it is reported with keen regret that Mr. Maxwell W. Day, who has been a member of this committee since its inception has found it necessary to retire from all business connections, and resigned from the committee early in the year. Mr. Day's personality and valuable technical experience has been a great asset to this committee through its entire life, and he has been greatly missed.

During the past year one paper has been presented at the Pacific Coast meeting, on the subject of electric propulsion. No doubt the coming year will see other papers prepared for presentation at some of the Regional meetings.

As to the work of the future, it is believed that the work of this committee will be very important in keeping these rules up to date, to conform to changes that develop with the advance of time and the development of the art. This will apply especially to interior communication apparatus, wire and cable, and personnel. It is also believed that considerable work is possible and desirable in connection with standard approval of fittings.

A very important factor in connection with the work of this committee is the cooperation between the work of this committee and other committees covering the manufacture of apparatus and appliances. The application to marine work requires certain refinements and rigid construction not necessary in ordinary apparatus, and for that reason the work of the Marine Committee must of necessity cover construction details more than is ordinarily considered the function of other industrial committees.

In conclusion, the chairman wishes to thank the committee as a whole, and the chairman of the subcommittees in particular, for their good work during past year, and the results which they have obtained.

---

Presented at the Annual Convention of the A. I. E. E. at White Sulphur Springs, W. Va., June 21-25, 1926.

Discussion at Midwinter Convention

THE RATINGS OF ELECTRICAL MACHINES AS AFFECTED BY ALTITUDE[1]

(FECHHEIMER)

NEW YORK, N. Y., FEBRUARY 10, 1926

R. E. Doherty: The accompanying Fig. 1 represents a generator. The cooling air enters at a temperature T_1. We are considering some spot, S, on the surface. There is a temperature rise of the cooling air which is occasioned by its passing over the heated surface before it reaches the spot in question. This brings the cooling air, the air to which the surface transfer is made at that spot, up to T_2. Then there is a rise of the surface temperature above that, which is T_3. There is a still further rise of the copper to T_4.

I wish to emphasize that Mr. Fechheimer's equations refer to some particular spot. T_3 is the surface temperature at that spot, and T_4 is the copper temperature. The temperature rise $(T_4 - T_3)$ is not a function of the barometric pressure. The temperature rise $(T_3 - T_2)$ is a function of the pressure, varying, let us say, as the 0.75 power. The rise $(T_2 - T_1)$ is also a function of the barometric pressure, but not the same function as for $(T_3 - T_2)$. It varies as the 1.0 power instead of 0.75.

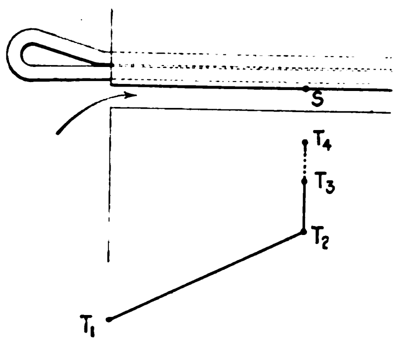

FIG. 1

The temperature rise of the surface spot, S, will depend upon the heat dissipated from it. Mr. Fechheimer's factor k, which corresponds to the factor a in the paper[2] presented by Mr. Carter and myself in 1924, is the fraction of the loss dissipated from the spot or surface which is due to $I^2 R$ loss. It should be observed that this is not the ratio of the copper loss in the machine to the total losses. There may be spots from which there is practically no heat due to $I^2 R$ loss, and others where all of it is due to $I^2 R$ loss. Hence, the table for k in Appendix II is without meaning until it is specified to what surface the values apply.

The author brings out the fact that there are two view-points from which this problem may be treated, which I should state as follows: One may take the temperature rise at sea level for a given load, and calculate the increase in temperature rise *for the same load and losses* when the machine is operated at altitude. The other is to calculate what reduction in load, and, therefore, losses, is necessary to give the same temperature rise as at sea level. The author takes the latter view-point; our paper in 1924 took the former. If correctly done, either gives adequate data for rules. I found the problem difficult enough without having to worry about the redistribution of losses and the necessary additional and very questionable assumptions required thereby. Since, however, the author's results check with those we obtained the other way, I naturally endorse it on the grounds of Dr. Kennelly's philosophy. If it is a convenient form of representation, and fits the facts, it is a perfectly good thing to do.

Now as to what Mr. Fechheimer says about my paper: "In the paper by Doherty and Carter, the exponent for forced convection was found to be 0.73 and to simplify calculations, they used 0.75. This seems to be correct for the machines for which they give data in their paper. As we understand their results, the exponent 0.75 takes account of the air rise as well as the surface transfer. It is felt, however, that their tests are too limited to warrant us to draw conclusions." He adds also that the results were of too complicated a nature to be used as a basis of engineering rules.

Our paper covered the general case. Convection, which is the only factor considered by Mr. Fechheimer, is not the total means by which heat is dissipated. Radiation may be a dominating factor. There are all grades between predominating radiation and predominating convection. Certain tests which I made, gave this figure 0.75, which checked with results on machines so far as they were available at the time. I still think it is about right. We took the rise $(T_3 - T_2)$ into account in a term which we called y. The rise $(T_2 - T_1)$ was accounted for in the term z. We properly combined the two results and called that x. We did not lump them, as Mr. Fechheimer has done, into one factor varying as, say, 0.9 power. It depends upon other factors.

Mr. Fechheimer says that our expressions are too complicated. The phenomenon itself is complicated of course, when the general case is considered. But after obtaining the equation for the general case, the specific data applying to a special case, such as Mr. Fechheimer has treated, may be substituted, and the resulting forms are extremely simple. Our paper gave these simple forms for various special cases, and the relation for the present case was a linear relation as simple as Ohm's law; and Mr. Fechheimer's numerical results, as shown in his Fig. 2, are in substantial agreement with ours.

So, his first point that the exponent 0.75 was taken as applying to both temperature rise, $(T_3 - T_2)$ and $(T_2 - T_1)$, isn't correct. They were not lumped together but were treated separately, and then logically combined.

Now, as to the point that results given were too limited for the drawing of conclusions: there may be justification of statement that they are too limited to draw *broad* conclusions, but I question his justification in saying they are too limited to draw *any* conclusions. We set up a logical theory under definite assumptions and then justified the conclusions by experiment. That is sound engineering. If it satisfies all the facts as they are known, it is reasonable to take the results as applicable within the limit of those facts and assumptions. That is just what we did. A rational theory was set up, taking into account not merely the condition of forced convection, but also the general case where part is radiation and part convection which takes into account the other details which may be thrown out or left in, as conditions may demand.

Then we made certain tests which checked up points on which existing data were insufficient, and applied that theory to actual machines under the conditions of pressure below atmosphere. The results agreed. Other tests were made on an actual machine in the field, first at sea level, then at high altitude. The data obtained on the machine were not complete, but such as were complete were in satisfactory agreement. So upon that basis I venture to suggest that our results are competent within the limits we specify.

I wish to say just a word about the several statements that equations are too complicated for A. I. E. E. rules. Of course they are. An investigation, which of course involves equations to determine a basis for framing simple rules, is one thing, but

1. A. I. E. E. JOURNAL, February, 1926, p. 124.

2. Effect of Altitude on Temperature Rise, by R. E. Dougherty and E. S. Carter, TRANS., A. I. E. E., 1924, p. 824.

making those simple rules is quite another. The present paper, covering one case, and our paper in 1924, which covers many, including that one, are such investigations. Mr. Paxton's proposal represents such simple rules. Therefore don't throw out results because there is an equation in them; otherwise you won't have anything upon which to build a simple rule.

P. L. Alger: An amateur reading Mr. Fechheimer's paper would probably be left with the impression that the effect of altitude on rating is greater than it actually is. For instance, Fig. 6 indicates that a very large reduction of rating may occur at high altitudes. But actual machines, designed for use at high altitudes, would be made with reduced flux densities and lower no-load losses than standard machines. Thus, it is more representative of normal conditions to take the total losses as proportional to the kv-a. rating than as a constant plus K times the square of the load. With this assumption, the effect of altitude on rating is reduced to that shown in Figs. 2 and 3 of the paper.

In the second place, the normal ambient temperature falls about 5.5 deg. cent. for each thousand-meters increase in altitude, or by nearly the same amount as the increase in full-load temperature rise of a normal machine due to the reduction of atmospheric pressure for the same increase in altitude. Therefore, if the cooling air is taken from outside the station, there is practically no change in rating required by change in altitude in the average case. Only when open machines designed for use in heated stations are considered is it necessary to allow for any reduction of rating. And even in these cases the maximum ambient temperature to be expected is certainly less than the maximum ambient temperature that may be met in sea-level operation, so that here, too, the reduction in rating need not be as great as that indicated by Figs. 2 and 3.

E. B. Paxton: I think we should thank Mr. Fechheimer for pointing out quite clearly the different ways in which the altitude correction may be taken into account provided there is sufficient information to do so. As he has said, the present A. I. E. E. rule takes into account only the case where the temperature rise is limited in a test near sea level by the amount of the correction for installation at a higher altitude. For this condition, the results that he obtains check, fairly closely, the results obtained previously by Mr. Doherty, as well as the present A. I. E. E. rule.

I think the present A. I. E. E. rule is faulty principally in that it takes care of that one condition only. It is my opinion that in a great many cases, a correction is made where it is unnecessary, and that, as Mr. Alger has pointed out, the ambient temperature will be sufficiently low to offset the correction necessary for the altitude.

This matter of correction for altitude would seem to be a relatively unimportant matter considering the many other conditions that affect the design and installation of a machine. For that very reason, we should be just as sure that any rule which is standardized does not require corrections unnecessarily as we are to cover the necessary cases.

Along this line, about a year and a half ago, I proposed a rule for inclusion in the A. I. E. E. Standards which is, I believe, an improvement on the present A. I. E. E. rule, in that it does take advantage of a reduction in ambient temperature at the higher altitudes and covers one of the cases which Mr. Fechheimer mentions in his paper. I think we must regard two kinds of applications: first, that of a standard machine, and we should make rules which will allow its application under all conditions where it may safely be used; second, we must recognize that there are conditions where it is necessary to use a special machine. I should like to see the present A. I. E. E. rule extended to allow the use of machines of standard temperature rise at high altitudes, provided the ambient temperature is low enough to compensate for the increased temperature rise. I am convinced that there are many cases where standard machines may be used safely at the higher altitudes without any correction.

W. F. Dawson: First of all, I want to suggest the probability of the ambient temperatures at high altitudes not necessarily being lower than at sea level. I have a record of certain tests on a 2550-h. p., 3600-rev. per. min., synchronous motor which I designed and tested some four years ago at our factory in Lynn, Mass., and repeat tests that were made in the Andes Mountains at an altitude of 14,000 ft. The ambient temperature during the mountain test in January was 21.5 deg. cent., which compares approximately with that in this vicinity. Of course, had that 14,000-ft. altitude been in the Canadian Rockies, the situation would have been different, but one must not forget that high altitudes exist also in tropical countries.

It seems to me that the crux of the situation is all ambient temperature. If the density of the cooling air, due to greater elevation, is lower than standard, its thermal capacity for a given volume is proportionately less. The average temperature difference between inlet and outlet air on self-ventilated turbine alternators at sea level will be between 15 deg. cent. and 30 deg. cent.

At the end of the test of the machine to which I have just referred, inlet air was 28.7 deg. cent. and outlet air 45.8 deg. cent., a difference of 17.1 deg. cent.

According to the formula used in Mr. Fechheimer's paper, the reference-air density was about 0.6 atmosphere which would mean that, at the 14,000-ft. station, the temperature rise of the air after passing through the motor would be 17.1 deg. divided by 0.6, or 28.5 deg., an increase of 11.4 deg., and that is slightly more than the temperature differences we ordinarily expect. It is unfortunate that, while we used temperature indicators at the factory, they were not available at the high elevation; but we did get a very good check on the field in spite of the fact that it was run at the higher current.

In turbine alternators, (and this synchronous motor is a turbine alternator fitted with a starting winding), one of the major losses of the machine is the windage loss. Windage loss will be from 0.3 to 0.5 of the total. In this particular case, at sea level the total loss passed through the machine at its rating, that is, the loss handled by the air, was 57.3 kw. Of that amount, 19.8 kw. was windage. What happened at the higher altitude? The 19.8 must be multiplied by 0.6 because the volume is the same at higher altitude as at the lower altitude, and the windage loss is in proportion to the density of the air, so 8 kw. of that loss are saved at the higher altitude. That is one of the credits of the problem.

The heating by increase in resistance of that field with 93.5 amperes at sea level was 40.8 deg. cent., of which 12.7 deg. was due to windage loss alone, leaving 28.1 deg. attributable to $I^2 R$. The test at higher elevation was run at 100 amperes. If we multiply that 28.1 by $\left(\frac{100^2}{93.5}\right)$, we obtain 32.3 deg. That will be the temperature rise due to copper loss, but the total temperature rise must allow also for the air friction. This will be no longer 12.7 deg. but 0.6 of 12.7 deg. = 7.6 deg. Adding this to 32.3 gives 39.9 deg. as the estimated field rise for the higher altitude. The value reported from Peru was 40.3 deg. cent.

My feeling is that the problem does not involve much of mathematics, but judgment combined with experience, and that it probably reaches its greatest simplicity in turbine alternators and similar machines where the air paths are systematically directed. The principal difference in temperature rise will be due to the fact that the ventilating air, because of lower density, will have a higher average temperature at the air-gap and where the windings are to be cooled; hence their temperature will be correspondingly greater.

The fact that the low-density air has a correspondingly less windage loss must not be overlooked. The full-load efficiency of the motor I have just been discussing was 96.45 per cent at sea level. About 8 kw. of windage loss was saved due to rarefied air at 14,000 ft. altitude, thus bringing the efficiency up to 96.84 per cent.

Sometimes it has been possible to apply the principal of the supercharger to machines which otherwise would have to be derated for operation at high altitudes. It is only necessary to provide special fans which increase the volume of air to correspond with its reduced density and thus insure the same temperature rise ordinarily obtained at sea level.

H. M. Hobart: I am of the opinion that from a standardization standpoint this subject will be best straightened out on the basis that the rating will be the available capacity of the machine at sea level. As Mr. Fechheimer suggested, sometimes you can take more out of the machine at higher altitudes, and sometimes less, according to the prevailing temperatures. That won't change the rating. The rating will be the available capacity at sea level and 40 deg. cent. cooling-air temperature.

G. E. Luke: The present A. I. E. E. rules (1925) for rotating motors and generators, (excepting railway motors), cover altitude limitations as follows:

"Unusual Service Conditions: The use of machines in cooling mediums having temperatures higher than 40 deg. cent. or at altitudes greater than 1000 meters (3300 ft.) should be considered as special."[3]

A similar statement is found for air-blast transformers; however, for self-cooled oil insulated transformers, the correction is 4/10 per cent per 100 meters instead of one per cent. From the wording of the footnote, ("it is provisionally agreed"), it is assumed that this correction was subject to doubt.

Both this paper by Mr. Fechheimer and a previous one by Messrs. Doherty and Carter[2] have brought out the fact that the altitude correction is considerably influenced by the ratio of copper-to-core loss and by the temperature gradient through the insulation. These factors are of considerable importance when temperatures are determined by embedded temperature detectors.

On the basis of certain assumptions, all of these factors can be

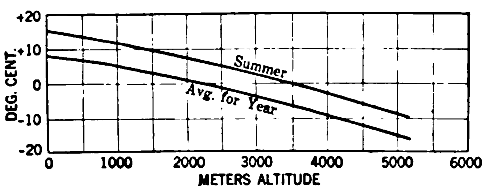

FIG. 2

combined into a group of equations; however, since some of the constants are factors of design, the equations are not in a suitable form for incorporating in the A. I. E. E. Standards.

In the discussion of the Doherty and Carter paper, Mr. E. B. Paxton suggested a plan whereby the maximum ambient temperature for various altitudes could be limited on the basis of a sea-level rating. Mr. F. D. Newbury's modification of this plan, I believe, offers a suitable solution for this unusual service condition. Naturally, such a simple solution is a compromise and is only approximate. It is warranted due to the very small per cent of machines operated at altitudes above 1000 meters (3300 ft.) and also to the average decreasing ambient temperature with increasing altitude. The accompanying Fig. 2 shows the average summer temperature at various altitudes taken near Paris, Brussels, Strassburg, and Munich, as given by the Smithsonian Physical Tables.

Where machines are to be operated indoors at high altitudes with ambient temperatures greater than those specified, the conditions should be regarded as special and the corresponding rating can be specified by the manufacturer as calculated by the method given by Mr. Fechheimer.

C. J. Fechheimer: It would seem that Mr. Doherty has understood me to be critical of the work which he has done. That is far from my purpose, for I appreciate the value of it. As he has pointed out, I have evidently mis-read one statement in his paper. Since he is considering the temperature rise of the surface above the air adjacent to it, and since his results and mine agree, there is no occasion for further discussion on this point; in fact, it is gratifying to note that we are in agreement.

With the simplified equation (36) in his paper, he takes account only of the surface drop and must then add the air temperature rise to it. In general, the air temperature rise is not known, particularly if it is taken from the entrance of the machine up to a particular point. Consequently, the purchaser of a machine is still considerably in doubt as to how to apply the equations. The method which I use, of taking a mean between the exponent, 1, for the air rise, and the exponent of about 0.75 to 0.80 for the surface rise, is not mathematically correct; nor with the possible variations in air temperature rise as compared with the surface drop, is it strictly correct to apply the method which I have used. My purpose was to place this complex subject on such a simple basis that the A. I. E. E. Standards Committee could embody it in its rules. Referring to Fig. 2 in my paper, it will be seen that the influence of the variation from an exponent of 0.75 to 1. is not very great; consequently, taking as an approximation a value of, say, 0.9, the error is not of great magnitude. After all, that is all with which we are concerned. In the present A. I. E. E. rule, as the total temperature rise is considered, it is not broken up into its two components, and in my opinion it will be necessary, in any revised rule, to follow this same practise.

Mr. Doherty refers to the constant k in my paper, which is the fraction of the loss in the core that is proportional to the square of the load at sea-level rating. In making up the tables in Appendix II, I considered that all the $I^2 R$ loss that was in the embedded part was liberated from the core, or from the straight parts of the coils, and that the end windings took care of themselves so far as dissipating their generated heat. That assumption may not be justified, and for accurate solutions, consideration should be given to the longitudinal heat flow along the copper and the transverse heat flow through the insulation. That, however, puts the problem entirely out of the range of a practical solution. Fortunately, this factor k disappears when only the temperature-rise ratios are considered. It appears in the equations when the ratio of ratings is solved for. After all, those solutions for ratings will be of value probably only to the designer and not to the purchaser of the machines, and the designer can approximate the percentage of heat generated in the embedded copper which is transmitted longitudinally or transversely. In the long-core machines, he will not introduce much of error if he considers all of the embedded $I^2 R$ loss to be liberated in the straight part. More of error is introduced in the short-core machine.

I confess that I do not understand how Mr. Doherty has reached the conclusion that I considered only the reduction in load, and not the increase in temperature. Equations (1) and (2) are solutions on the basis of temperature. Equations (3) to (6) are on the basis of ratings.

It is true that I have considered forced convection only. In the majority of machines in which fans or their equivalent are used, radiation may be excluded, and even free convection is of little consequence. My paper is not intended to cover such apparatus as self-cooled transformers or motors which liberate a large percentage of their heat through the outside casing by radiation or free convection. The statement which I made in my paper, to which Mr. Doherty refers, *i. e.*, that the equations in his paper were complicated, was prompted by such equations as (18) and (30), the former covering the general case and the latter the case for forced convection. My whole

3. "For apparatus intended for service at altitudes greater than 1000 meters (3300 ft.) it is provisionally agreed that the permissible temperature rises (to be included in contracts and checked by test at low altitude) shall be less than specified in these standards by 1 per cent of the specified rise for each 100 meters (330 ft.) of altitude in excess of 1000 meters (3300 ft.)."

purpose in writing the paper in the manner as presented was to place it in simple form before the members of the Institute.

Mr. Alger states that by reducing the flux densities, the ratings need not be reduced. That is undoubtedly so, but in many cases, machines with standard windings will be applied at the higher altitudes, chiefly to save the expense of making special machines. The other point that Mr. Alger makes in regard to ambient temperature, would I think, bear further study. While it is true that we have, from the Bureau of Standards, data on ambient temperature, and, as Mr. Luke points out in his discussion, from parts of Europe, a more thorough study of this whole subject could be made by the Standards Committee in order to offer suitable recommendations. Undoubtedly, in many cases the lower ambient temperature will practically off-set the loss in rating that would otherwise be occasioned by the lower density.

Mr. Paxton's comments are largely along the same line of ambient temperature. He previously contributed valuable material in his discussion of Mr. Doherty's paper, and his suggestions are worthy of study by those who will participate in the revision of the rules.

The point that Mr. Dawson makes, that the ambient temperature at 14,000-ft. elevation in January was 21.5 deg., is of considerable interest. However, January is summer in South America, and the particular locality was not far from the equator. The specific machine upon which he had tests made, *i. e.*, a turbo alternator for which the windage loss decreased considerably, is undoubtedly a special case and cannot be treated along with the general cases. While special fans may be added to increase the volume and thereby obtain lower temperature rises at the higher altitude, in general such a scheme is not to be adopted, as it would make the machine so highly specialized that the manufacturers would seldom go to the expense, nor would the customer wish to pay for it.

Since writing the paper, my attention has been called to a rather unusual phenomenon. It is claimed by some of the railway engineers that in a-c. commutator motors, brush-friction loss decreases with increase in current. It is even claimed that some of these commutators run cooler at normal full-load than they do at no-load. I am offering no explanation for the cause of this phenomenon, but, assuming that the statement is correct, the correction for altitude as given for commutators in Appendix IV no longer holds. Not knowing the rate of decrease in brush-friction loss with increase in $I^2 R$ loss, it is impossible for me to suggest a solution to that part of the problem.

One other item of comparatively small importance was not considered in the derivation of the equations. With lower ambient temperature, the air density is increased; with increase in density, both the air-temperature rise and the surface drop decrease. At the higher altitudes, if the ambient temperature is lower, the rating of the machine is not decreased so much as indicated by the equations. It is believed, however, that this additional correction need not be given much consideration.

MOTOR BAND LOSSES[1]

(Spooner)

New York, N. Y., February 10, 1926

G. E. Luke: In particular I remember one experimental machine designed for high-speed railway work that gave considerable trouble due to the bands coming loose. Some attributed this to the high centrifugal stresses; however, later tests proved the trouble to be due to excessive band losses. Careful insulation of these bands reduced the stray losses and no more such trouble was experienced. After Mr. Spooner had completed his first tests on band losses I arranged tests on a 50-h. p. railway motor. Small thermocouples were soldered to the bands and others placed on the winding and core. These couples were brought out to special slip-rings so that the temperature could be determined with the motor running. In this way tests were made with insulated and uninsulated armature bands. An appreciable temperature difference was found between the two tests. In some cases the uninsulated armature had temperatures 10 deg. cent. higher than that armature with insulated bands.

1. A. I. E. E. Journal, January, 1926, p. 14.

Due to the many other losses and factors that must be controlled, work of this nature must be done with a high degree of accuracy and requires considerable patience on the part of the experimenter. Mr. Spooner has also put the data in such form that they can be used in determining the losses on other machines of similar design.

J. C. Lincoln: Some years ago, a case of trouble from bands throwing solder was solved in the following manner: In this particular case the machine was an eight-pole machine and the bands, as is customary, were soldered entirely around the armature. The trouble was corrected by placing four strips for holding the wire of the bands together at 90 deg. around the armature and soldering the bands only where these strips were placed. This left a north pole and a south pole between each of the strips and the bands were not soldered between these strips. The total magnetic induction between the bands was zero.

In other words, between each typing strip there was a north pole and south pole and therefore there was no voltage induced in the bands between each of the tie strips. As the result of this change, the machine which had been throwing solder around the bands and giving trouble was corrected entirely.

P. L. Alger: I should like to ask Mr. Spooner if he has made a study also of the losses in the binding bands on the end conductors of rotating armatures, and, if so, whether such losses are ever large.

Thomas Spooner: Replying to Mr. Alger's questions, we have never investigated systematically the losses occuring in bands which hold the end windings of machines in position. These losses are often appreciable but we have no quantitative data concerning them.

In the case of Fig. 2 of the paper, the losses there given are for the unwound armature. If the armature windings had been in position, as they were for certain later tests, the losses would have been higher, due to eddy currents in the copper.

PROPERTIES OF THE SINGLE CONDUCTOR[1]

(Hering)

New York, N. Y., February 11, 1926

S. L. Quimby: In the classical electromagnetic theory, self-inductance is specifically defined and invariably calculated as a property of a complete electric current circuit. No theory consistent with the facts revealed by experiment has yet been developed to make possible the calculation of the self-inductance of any portion of a circuit.

I now propose to analyze the two experiments described by Dr. Hering and to point out the way in which the energy relations derived by him differ from those which are in accord with the electromagnetic theory.

I shall first consider the second of these experiments. Dr. Hering bases his analysis of this upon a theorem ascribed to Lord Kelvin. This theorem states that if any system of current circuits in which the currents are kept constant by batteries is allowed to alter its configuration, then, of the work done by the batteries in keeping the currents constant, one-half will appear as increased magnetic energy of the system of currents and one-half as mechanical work.

Fixing our attention upon Dr. Hering's apparatus, we imagine that, initially, the weight is locked rigidly in place and furthermore that the whole conductor is perfectly rigid. A current flowing in this conductor now supplies us with a definite system of

1. A. I. E. E. Journal, January, 1926, p. 31.

current circuits, namely, the very large number of filamentary conductors into which the finite conductor may be imagined to be divided. With the weight still locked in place, we now suppose that the conductor is no longer rigid, but elastic. Under the action of the pinch forces, it will shrink, radially. Its self-inductance will therefore increase by an amount ΔL, and the magnetic energy of the system will increase by an amount $1/2 \ . \ \Delta L \ . \ i^2$. At the same time, a certain amount of mechanical energy is stored in the elastically strained conductor. Kelvin's theorem tells us that this energy of elastic strain is precisely equal to the increased magnetic energy. The radial displacement of the material of the conductor accompanying the shrink involves a cutting across the lines of magnetic force in the conductor, and the counter e. m. f. thereby developed accounts for the work done by the battery in supplying the elastic energy.

This is as far as Kelvin's theorem carries us in our analysis, for, if we now release the weight, it will move and this motion will cause the introduction of *new conducting material into the circuit*. We no longer have a definite system of conductors to consider but instead a system which is continually changing through the continual introduction of new conductors. Kelvin's theorem can no more be applied to an analysis of this machine than it could to an analysis of an ordinary d-c. motor, in which, barring resistance, all the energy supplied by the battery appears as mechanical work and the magnetic energy remains practically constant; and this for the same reason, since the commutator on a d-c. motor is merely a device for continually introducing new conducting circuits into the system.

The introduction of new mercury into the conducting system involves a radial flow across the lines of force in the conductor and it is easily shown that the work done by the battery against the counter e. m. f. thereby developed is precisely equal to the mechanical energy acquired by the raised weight.

Dr. Hering's analysis of his first experiment is based upon an assumption which, in the light of the electromagnetic theory, is false. He assumes that if the pinch pressure is allowed to annihilate a fluid-conducting circuit of the type described, then the mean pressure, *i. e.*, the pressure at a distance $R/\sqrt{2}$ from the axis of the conductor, will be constant. This, as the author shows, is equivalent to the assumption that the current will decrease linearly with the radius. Calculations based upon the electromagnetic theory show that under the conditions of the experiment the variation of the current with the radius of the conductor as it collapses would be given by the expression

$$I = [\log (2\, p\, l/R)]^{-1}$$

where

$$1/p = \log^{-1} (3/4),$$

and

l = the length of the conductor.

In conclusion it may be observed first, that the classical electromagnetic theory has never concerned itself with the calculation of the self-inductance of, nor the energy associated with, a unit length or any other portion of a current circuit, and second, that the argument by which the author arrives at his value of these quantities is not consistent with that theory.

A word should be said on behalf of the self-induction formulas supplied by the electromagnetic theory. Where these are calculated for the simple circuits, of whatever size, referred to by the author, they do not necessarily contain approximations, never involve empirical constants, and are never derived by extrapolation.

The author, if I understand him correctly, maintains that the process of evaluating the total magnetic energy in a certain space by integrating the Maxwellian energy density $H^2/8\pi$ throughout that space, is valid only when the magnetic field is uniform in direction. It seems to me that this criticism lacks weight. Consider, for example, a circuit consisting of a straight cylindrical conductor with a return through a concentric cylindrical conducting sheath. I doubt very much whether Dr. Hering will deny that the energy associated with such a current circuit can be obtained correctly by integrating $H^2/8\pi$ throughout the volume enclosed by the sheath. And yet this is precisely the type of field for which he denies the validity of this procedure. The argument which he uses in support of his contention is not, in my opinion, a good one. To adopt one of his own analogies, it is quite true that the pressure at the bottom of a column of bricks cannot be obtained by adding together the pressures at the bottoms of successive strata, but the total potential energy of the column most certainly can be calculated by summing up the separate potential energies of the different strata.

B. A. Behrend (communicated after adjournment): Dr. Hering's paper is a critical review of fundamental electrical principles and an attempt is made to call attention to, and suggest a different attitude toward, certain phenomena and experiments which in the conventional treatment appear distinctly awkward.

It has been known, of course, to the earnest and profound student, that unipolar or homopolar induction and allied phenomena strain somewhat the fundamental simplicity of Faraday's law of induction as given to us in its mathematical form by Maxwell. But Maxwell and his interpreters were aware of this, as was pointed out forty years ago by Oliver Lodge in his "Modern Views of Electricity." I discussed some of these difficulties with Prof. Lodge about 1890 and retain his pencil memoranda on the subject.

Attempts to compare the fundamental phenomena of electromagnetism to related phenomena in hydrodynamics and the theory of elasticity have proved useful. Temperature and electric and magnetic potential and the velocity potential appear as complete mathematical parallels. Lord Kelvin and Professor P. G. Tait have established the identity of mathematical conditions in St. Venant's torsion problem and a hydrokinetic problem.[2] Professor A. E. H. Love has also worked out the hydrodynamical analogy in which the problem of torsion of a twisted prism is compared with that of a frictionless liquid in a rotating cylindrical vessel or with liquid circulating with uniform spin in a fixed cylindrical vessel coinciding with the surface of the twisted prism.[3]

What I propose to point out here is that a similar complete analogy exists between the electromagnetic phenomena cited by Dr. Hering and the phenomena of torsion of prisms as treated by de St. Venant. The value of such analogies lies in creating mental pictures and substituting for unfamiliar problems those to which we have grown accustomed.

So far as I understand the Faraday-Maxwell electromagnetic theory and the ideas recently propounded in several papers before the Franklin Institute and this Institute by Dr. Hering, I daresay that Dr. Hering's views, far from being contradictory of the conventional theory, give an additional physical interpretation and expound some of the obscurities and difficulties of the traditional theory. Guided by his own views, Dr. Hering has made some valuable inventions which in themselves speak well for his point of view, and it seems as though both Bourbon and tyro of our art might well lend an open mind to these papers and to Dr. Hering's interesting and thoughtful experiments.

R. P. Jackson (communicated after adjournment): I was much interested in the statements of Dr. Hering in the February JOURNAL, page 123, concerning comparisons of the inductance of a circular circuit with that of a straight conductor of equal length. Some years ago I made an investigation of similar character and came to approximately the same conclusion.

At that time, I was investigating the requirements of conductors to and from lightning arresters. A great deal has been said about the increased impedance of bends and angles in such conductors and of the necessity of maintaining straight lines or easy curves and avoiding sharp bends. A little investigation

2. Treatise of Natural Philosophy, by Kelvin and Tait, part II, p. 242.

3. A. E. H. Love, Treatise on the Theory of Elasticity, Vol. I, p. 158 et. seq.

demonstrated that as soon as you begin to curve a conductor away from a straight line you begin to reduce its inductance per unit length and that a single-turn loop could not possibly have as much inductance as the same conductor run in a straight line, far from any return circuit.

This conclusion, of course, does not entirely remove the objection to curves and bends in lightning conductors for the simple reason that a straight line is the shortest distance between two points. For that reason, being the shortest conductor, one following a straight line will probably have less inductance than any other conceivable path would afford.

The presence of necessary angles and bends is harmful only in so far as the total length of the conductor is increased and their harmful effect may be much less than ordinarily assumed, providing, however, the conductor itself is of proper section and shape.

It is apparently more important to avoid single, small cylindrical conductors than it is to fear convenient and necessary curves and bends in connection with high frequencies. When there is more than one turn, however, the condition is entirely changed as the same flux threads through the various turns and there is the well known approximation, depending on the relative position of the turns, for the inductance to increase with the square of the number of turns.

(EDITOR'S NOTE: Following the presentation of the paper M. F. Skinker read from an article by Leigh Page, published in the *Journal* of the Franklin Institute for February, 1926, page 245, which article discussed a former article by Dr. Hering in the same *Journal*. Dr. Hering's reply to this is published in the April issue of that *Journal*, page 497.)

A HIGH-FREQUENCY VOLTAGE TEST FOR INSULATION OF ROTATING ELECTRICAL APPARATUS[1]

(RYLANDER)

NEW YORK, N. Y., FEBRUARY 11, 1926

C. T. Weller: About ten years ago we started to investigate the effect of high-frequency discharges through the windings of standard types of current transformers. This investigation led to the development of the by-pass protector. The outfit developed at that time has proved to be very satisfactory for work of this nature. Referring to Fig. 2A in Mr. Rylander's paper, we found the quench-gap to be the most suitable for our purpose, the setting being obtained by varying the number of units in series. We utilize an adjustable air-core reactance in series with the test device to vary the frequency in the oscillation circuit and the voltage across the test device, the total voltage being fixed by the setting of the quench gap. We utilize two crest voltmeters, each consisting of a kenotron and an electrostatic voltmeter for measuring voltage and detecting breakdown. One crest voltmeter is connected across the series reactance and the other across the test device, the test voltage being held on the latter. In case of breakdown, the voltage across the series reactance rises while that across the test device falls. The changes in voltage are accompanied by a change in frequency. The approximate frequency is determined by means of a wave meter coupled inductively to the series reactance. Some difficulty has been encountered in arriving at this determination, however, due to harmonics in the oscillation circuit. However, the frequency is not so important with this outfit since the main reliance is placed on the crest voltmeter. The crest voltmeter has an advantage over a spark-gap in that it will indicate the crest value of the voltage at all times during the test. The outfit described may be used for testing the insulation of the windings of a wide variety of apparatus at high frequency.

V. M. Montsinger: The testing of coils between turns by means of voltage at high frequencies has been practised for years by the company with which the speaker is connected. We have used for that purpose damped oscillations and for detectors we have used a telephone receiver and an ammeter. A diagram of the arrangement for testing with damped oscillations of 20,000 cycles per second is shown in the accompanying illustration.

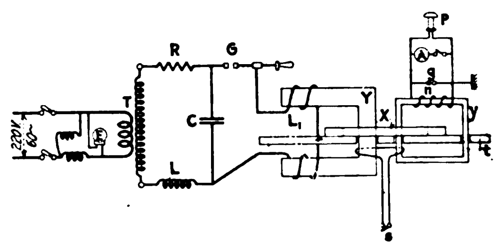
The charging circuit of the condenser C consists of a resistance R, an inductance L, and a step-up transformer T. The transformer T is excited by means of an induction regulator so as to obtain a voltage control of $E = 0$ to 440 volts from a 220-volt, 60-cycle supply.

The discharge circuit of the condenser C consists of a spark-gap G and an inductance L_1 which also serves the purpose of a linking coil, or excitation coil, of the testing yoke, Y. The discharge circuit of the condenser has a natural frequency of about 20,000 cycles per sec.

The coil X to be tested is placed on the table t in such a manner that the coil encircles both the testing yoke Y and the detector yoke y. Both of these yokes are of split construction so that the coil may be inserted. Yoke y carries a coil n of only a few turns connected to a phone receiver P and to a hot-wire ammeter A.

When the spark-gap, G, is arcing, the condenser voltage is discharged across the linking coil L_1 and an oscillating voltage at a frequency of about 20,000 cycles is induced in the coil X under test. When the coil under test is perfect, or when it withstands the induced voltage test, the phone receiver will be silent and the ammeter will indicate zero.

However, the phone receiver will be noisy and the ammeter



ARRANGEMENT FOR TESTING COILS WITH HIGH-FREQUENCY VOLTAGE

will indicate a deflection when the coil under test is defective or when it breaks down during test, because then a short-circuit current in the defective coil will magnetize the detector yoke y and energize its coil n.

A small gap, g, with one terminal grounded is provided for the protection of the indicating instruments.

One auxiliary turn mounted under the table, encircling the testing yoke Y and the detector yoke y, may be short-circuited by the switch s at any time to show whether or not the equipment is operating satisfactorily.

The voltage per turn induced in the coil under test is directly proportional to the voltage E impressed on the transformer, provided that the setting of the spark-gap G is maximum for the discharge voltage of the condenser.

This testing method offers high induced test voltages per turn at the high frequency of about 20,000 cycles per sec. This frequency does not overheat the insulation because each train of damped oscillations, which starts at every half cycle of the supply frequency ($2 \times 60 = 120$ times per sec.), lasts a very short time only and is followed by a comparatively long period of rest.

Experience has demonstrated that this outfit is a practical shop method for inducing high voltage between turns. It does not require an experienced person to operate it and will not only detect weak points of insulation but will give evidence of corona discharges.

E. S. Lee: Mr. Rylander has described a somewhat modified form of a method which, as has been indicated by other speakers,

1. A. I. E. E. JOURNAL, March, 1926, p. 217.

has been variously used during the past eight or ten years. Where it is desired particularly to obtain a high enough voltage between the individual turns of a coil to enable weak spots in the insulation to be broken down, the use of high-frequency voltage is advantageous, as higher voltages are thereby obtainable between turns than with the usual methods employing low-frequency voltage.

It is my understanding that this becomes a comparison method; that is, a coil is selected which is considered a good one and if the reading on the instrument for other coils approximates the reading as given by the good coil, then these coils may be assumed to be suitable and fit for use. If, on the other hand, the reading on the instrument does not closely approach the established reading, there is something wrong with the coil and if the voltage is high enough to cause a breakdown of the insulation, it will be easily detected.

I should like to ask Mr. Rylander how important it is to maintain the relative positions of the coil under test and the tuning coil. If we use this test for more complicated structures, as suggested by Mr. Rylander, how great a factor will be introduced because of the relative difficulty of placing the detector coil in about the same relative position with respect to the coils to be tested, since these may be assembled into stators of different sizes and forms? I believe this condition will have to be taken into account.

Mr. Rylander's paper quite clearly brings out the many defects which may occur in the manufacture of the insulation. If it is found that quite a bit of trouble is arising from these factors, then such a test as has been described is probably necessary. If, however, there are no troubles from these, it is a question whether or not such a test ought to be applied. This is true particularly because it is not altogether simple to determine the exact voltage distribution in the different turns of the coil. Mr. Rylander speaks of this in the paragraph in which he says, "In general, the voltage builds up somewhat on the end coils." Also, in so far as we do not know definitely the conditions that exist in the coils due to surges, we are not absolutely sure that by applying a high-frequency test, we are applying a test that is comparable to service conditions. It may not necessarily have the same characteristics, and we must be sure to have the same characteristics.

I think that this test must be put in the same category with any other test. In the section entitled *Benefits Derived from High-Frequency Testing,* Mr. Rylander states many defects which this test has shown to exist in the coils which he has tested. I think that Mr. Rylander wishes to bring out that this form of testing will show that some defect is present, or, if breakdown occurs, will allow such evidence to remain that the cause of the failure may be ascertained by visual inspection. Although where required, the test as indicated is of value, still of itself it does not show the cause of failure.

G. E. Luke: The A. I. E. E. standardization rules give limits for test voltages between circuits and grounds, but nothing is said concerning test voltages between turns. The reason for this omission is that there has been no standard or established method for conducting this inter-turn dielectric test. This paper and the discussions show that the manufacturing companies recognize the importance of this insulation and are developing means for testing its factor of safety.

In my experience on dielectric tests of windings there have been some puzzling breakdowns between turns; especially do I remember one series of armatures that gave a high percentage of failures between end connectors. Although the clearance was small, the insulation should have withstood a potential of 1000 volts or more, but some failed on a low voltage of from 50 to 100. In this particular case, the trouble was due to insufficient drying of the impregnating varnish or compound. A high-frequency test, such as described, would reveal such a weakness, whereas, without such a test, the machine would be passed as correct. Anything we can do to improve the methods for testing insulation, particularly that between turns, will be of great value to the electrical industry.

J. L. Rylander: Mr. Montsinger has described a method of testing individual coils with induction and the use of high frequency. I wish to point out that that method of test has no similarity in principle to the test described in my paper either as to method of applying the voltage or to the method of detecting failures; and furthermore, it is very limited in its application, as will be explained later. I understand that the test referred to by Mr. Weller and Mr. Lee is the same as that described by Mr. Montsinger as regards the method of applying the voltage; and for detecting breakdown, they use a crest voltmeter instead of the telephone receiver used by Mr. Montsinger.

With the method described by Mr. Montsinger, the voltage is applied to the coil under test by "induction," the coil under test acting as the secondary winding of a transformer. With the method described in my paper the high-frequency high voltage is applied *directly* to the coils or completed windings or other apparatus under test, as shown in Figs. 1 to 8 of the paper.

For the method of detection, Messrs. Weller, Montsinger and Lee use telephone receivers or crest voltmeters instead of the wavemeter shown in Fig. 2B of the paper.

The merits of the directly applied, high-voltage high frequency as compared with the induction method are as follows:

1. It can be applied to completed or partially wound machines as well as to coils of any type or shape, large or small, armature coils, field coils, magnet and other types of coils. The test shown in Mr. Montsinger's diagram is not and cannot be applied to completed a-c. windings; nor can coils be satisfactorily tested if the coils have a very small or a very large opening into which the testing yoke and the detector yoke must pass.

2. Invariably, the cause of any failure can be ascertained. The reason for this is that when a defect occurs, the insulation is burned away only at a small spot between the turns at the defect. With the induction method of test, the result of a defect is that the short-circuited turns are heated to a very high temperature the full length of the turns, so that the insulation is charred the full length of these turns as well as on the adjacent turns; and, as a result, the exact location of the defect cannot be determined; and usually the evidence of the cause is destroyed.

3. This directly-applied test corresponds to service conditions. Current flows in the coils or windings and also voltage is impressed between the turns, and the high-frequency oscillations correspond to the service surge effects upon any particular winding.

4. The wavemeter method of detecting failure, as used with the directly-applied, high-voltage high frequency, is an adequate and most effective method of detecting short circuits and insulation breakdown.

Mr. Lee asked about the importance of the location of the wavemeter tuning coil in respect to the coil or more complicated structure under test. This is a very important feature. Our wavemeter readings consist of the frequency as determined by the inductance and the condenser setting at resonance, and to the intensity and direction of the transmitted electromagnetic field as shown by the ammeter reading and the distance from the wavemeter tuning coil to the apparatus under test. Therefore, the reading for a defective piece of apparatus is different from the reading for the same apparatus without any defects. However, the point should be brought out that even when there is only one piece of apparatus to test, it can be tested and the readings will indicate whether the winding is satisfactory or whether defective. There is no difficulty in placing the tuning coil in the same relative position with respect to the apparatus under test. Mr. Lee stated that my paper "brings out clearly the many defects that may occur in the windings." We have found since we started this method of test that every one of the defects mentioned did occur, although we did not know it before.

Mr. Lee pointed out that it is difficult to determine the exact voltage distribution in the different turns of the coils. When we test a particular type of winding for the first time, we place a crest voltmeter across the end coils or others and measure the voltage on them while the voltage is applied to the leads. We can now estimate very well how it does divide on apparatus which is similar to something we have already tested. It should be pointed out, however, that a knowledge of the approximate voltage distribution in a winding (easily obtainable by this test method) is significant from an operating standpoint rather than from a testing point of view.

In conclusion, it may be stated that, by means of this directly applied high-frequency high-voltage test, the "internal" parts of windings can now be tested as thoroughly as the "external" insulation is tested by the "ground" test.

THE MAGNETIC HYSTERESIS CURVE[1]

(Lippelt)

New York, N. Y., February 11, 1926

S. L. Gokhale: I believe that Mr. Lippelt's analytical conception of reactive and dissipative components of magnetic forces within a magnetic material, if carried to its logical consequence, will eventually do for the magnetic circuit what the conception of "energy component" and "idle component" have done for the electric circuit. Mr. Lippelt also deserves credit for his ingenious method of evolving from an unsymmetrical hypothetic equation another of symmetric form. This method is likely to have a very wide and useful application in other fields.

As to his equation (7) which is one of the two important equations in the paper, I take the liberty of disagreeing with the author. His line of reasoning, as I understand it, is as follows:

a. Near saturation, hysteresis practically disappears, making $R = -H$.

b. Near saturation, the relation of H to β follows the law $H = +K/\gamma$.

c. Therefore, near saturation, the relation of R to β must also be represented by the law $R = -K/\gamma$.

Mr. Lippelt's final equation for the magnetic hysteresis curve de-

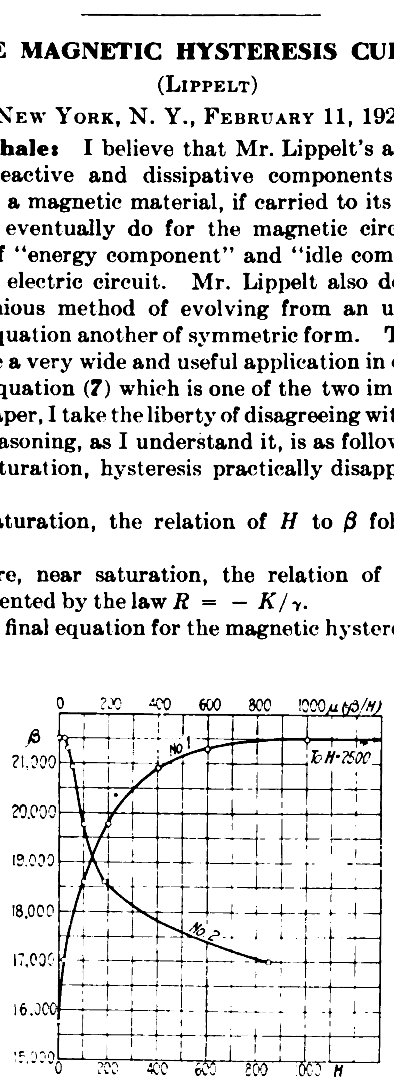


Fig. 1

pends entirely on proposition c, and therefore ultimately upon proposition b, which he accepts as an established and indisputable fact.

At this point I differ from Mr. Lippelt. I have in my hands a few hundred magnetization curves, to demonstrate that the relation of H to β cannot be represented correctly by the equation, $H = K/\gamma$; that relation can be represented much more closely by the equation $\log \gamma = f - g H$, or $H = a - b \log \gamma$. It is not possible to present the full evidence in a brief discussion like this, and I shall therefore limit myself to a single illustration for the present.

Fig. 1 represents the curves for intrinsic induction (Curve No. 1) and permeability (Curve No. 2) for a sample of electrolytic iron. This sample was included in a paper by Dr. Yensen.[2] The sample was tested at the Bureau of Standards, Washington. The material as well as the test data are therefore of the highest possible reliability. A study of Curves 3 and 4 of Fig. 2 shows conclusively that the relation of H to β for this material does not follow the law $H = K/\gamma$, but instead, follows the law $\log \gamma = f \dot{-} g H$. As this material has a remarkably low hysteresis, it follows that near saturation, the hysteresis should be prac-

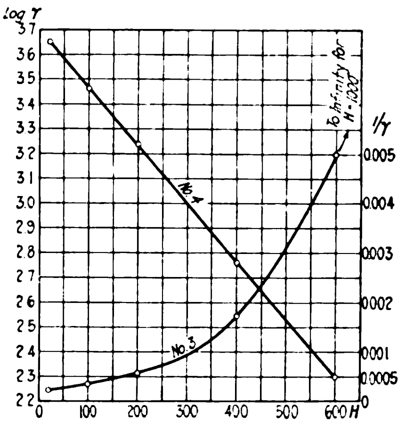

Fig. 2

tically negligible so as to suggest that the true law of reactivity should be $\log \gamma = f + g R$.

If, after a careful study of these and several other curves, Mr. Lippelt decides to revise his views as to the equation of reactivity near saturation, he might have to revise his equation for hysteresis also.

As to the equation for the dissipative component, *viz.*,

$$D = -A/\cosh \theta$$
$$= -A/\cosh \left\{ (c H + f) + q \sqrt{h + (c H + c f)^2} \right\}$$

I notice that the term βh,—that is, the peak value of β for the hysteresis loop,—is conspicuously absent. We all know that hysteresis depends in some way on the peak value of β; any formula for hysteresis in which βh is absent is, therefore, not likely to be the true formula, even approximately. On this point, I believe we need some explanation before we could accept Mr. Lippelt's equation.

In the course of the presentation of his paper, Mr. Lippelt claimed to have established a rational equation for hysteresis; I am unable to follow him at this point. If I understand his argument correctly, he has attempted to formulate a rational equation for R and an empirical equation for D.

In Section VII (Applying the Theory), the author shows that Kennelly's law of reluctivity follows as a corollary from his theory.

Kennelly's law is only another form of Frolich's law. Mr. Lippelt's hypothesis is admittedly a form of Frolich's law, and must necessarily agree with all other forms of that law, including Kennelly's law. Such agreement implies nothing more than this—that any hypothesis in harmony with any other hypothesis will agree with that hypothesis in all its forms. Such an agreement has obviously no evidential value in support of the hypothesis in question.

Mr. Lippelt's hypothesis ($H = K/\gamma$) is analogous to Boyle's law for perfect gases. But in formulating the law on this basis he has to assume that magnetization consists of charging the

molecules with something that is not in the molecules to start with, *viz.*, the magnetic induction β. Such an explanation of the equation would therefore be in agreement with Poisson's theory, but not in agreement with Weber's theory, which is, at present, the generally accepted theory.

TABLE I
MAGNETIZATION TESTS ON ELECTROLYTIC IRON

Test made at the Bureau of Standards—Test No. Tem. 41893. Data for H and B received through courtesy of Dr. T. D. Yensen. The other columns of the table are obtained by computation.

H	B	β	γ	μ $(=\beta/H)$	$1/\gamma$	Log γ
0.2	460					
0.4	4600					
0.5	7300					
1.0	11150					
2.0	14230

2000.0	23500	21500	0	10.7	inf.	
2500.0	24000	21500	0	8.6	inf.	

Notation: In this table
$\beta = B - H$
$\gamma = S - \beta$ (Where $S = 21500$).
$\mu = \beta/H$ (Intrinsic permeability).

Hans Lippelt: It is obvious that in presenting this paper I did not intend to advance a final and conclusive treatise on magnetism. Of the experimental data which I had on hand, only those appertaining to one magnetic cycle of tungsten steel appeared to be best suited for the study. With such fundamental limitations, it cannot be expected that the results obtained and conclusions drawn will cover all possible cases of magnetization. This state of affairs is reflected in Division 10, under "Conclusions," by the statement that Equation (7) is hypothetical. At the same time it should be noted that this equation is rather plausible and is also rooted in well-known laws of physics. Mr. Gokhale's apprehension that Equation (7) is "indisputable" does not seem to be claimed in the paper.

Mr. Gokhale expresses his disagreement in particular with Equation (7) and rests his point of view on research work of his own and on premises mentioned under a and b and on a conclusion, c.

In deriving Equation (7), use has been made of the relation $R = -\dfrac{K}{\gamma}$, but it has been used merely as a stepping stone for evolving Equation (7), which constitutes the improved form of the relation between R and γ.

The paper in exploiting the test data makes *no use* of Mr. Gokhale's relation c: $R = -\dfrac{K}{\gamma}$, but employs Equation (7) exclusively. The effect will be understood when, for example, both relations are applied to the case of $\beta_h = 13183$, the highest value of magnetization which the tungsten steel attains in its magnetic cycle.

$$\text{Mr. Gokhale's relation (c) } R = -\frac{K}{\gamma} = -\frac{K}{S-\beta}$$

$$= -\frac{0.5682 \times 10^6}{16000 - 13183} = -202 \text{ wrong value}$$

$$\text{As per Eq. (7) of paper, } R = -\frac{2 \times 0.5682 \times 10^6 \times 13183}{16000^2 - 13183^2}$$

$$= -182 \text{ correct value}$$

The difference amounts to 11 per cent of the true value.

Referring now to Curves 1, 2, 3, and 4 submitted by Mr. Gokhale, essential characteristics of those curves, not mentioned yet, should be stated before making further use of them. The equation of Curve 4 is

$$\log \gamma = \log (S - \beta) = 3.6996 - 0.002331 \times H \qquad \textbf{(d)}$$

from which follows (see also Curves Nos. 4 and 1).

for $H = 0$ $\gamma = S - \beta = 5007$ and therefore $\beta = +\beta_0 = +16500$
for $H = 1588$ $\log \gamma = 0$; $\gamma = S - \beta = 1$ $\beta = 21500 - 1$

simultaneously $\left.\begin{matrix} H = 0 \\ \beta = 0 \end{matrix}\right\}$ would make $\gamma_o = S$ and $\log \gamma_o = 4.3324$ which is not situated on the straight line No. 4.

The fact that for $H = 0$ a residual magnetization $\beta_0 = +16500$

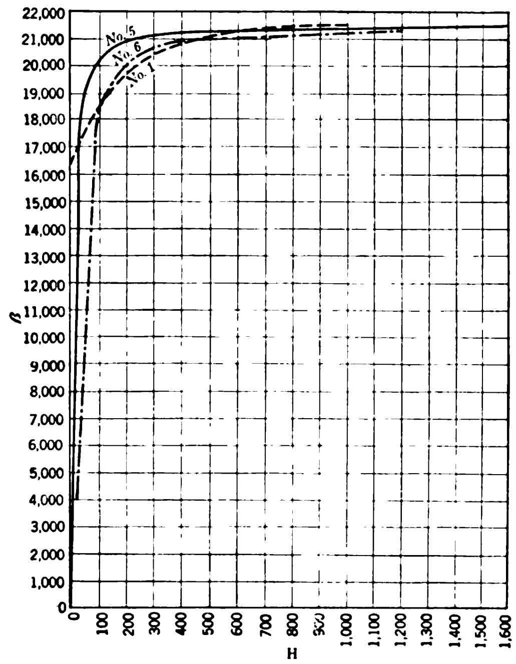

FIG. 3

occurs, renders the cited curves unsuitable for comparison with the hysteresis curve of the paper. Curve 1 looks more like the descending branch of a hysteresis curve, while Table I showing test data indicates that the H-values progressed from $H = 0$ to 2500, characterizing it as an ascending branch.

Due correction should be made, because "Weber's theory" also implies that the magnetizing effect of a field H depends on the configuration of molecules at the beginning of the process.

On the other hand, if the low hysteresis is to be neglected altogether, there should be $\beta = 0$ for $H = 0$.

Fig. 3 herewith has been drawn up to facilitate, as far as possible, comparison between Mr. Gokhale's results of research and the theory of the paper. Curve 1 has been copied from Mr. Gokhale's Fig. 1, and Curve 5 is a magnetization curve computed on the basis of Equation (7), or rather Equation (15), which is another form of Equation (7) of the paper. Numerical values are given in Table II. K as it appears there is a value adapted by mathematical trial to Curve 1.

Now inspecting Fig. 3, if, as called for, Curve 1 were duly corrected to start at the origin of the system, the two curves 1 and 5 would be close together for values of β from 0 to about 18,000 and from 21,000 to saturation. A difference, however,

TABLE II

Comparison of Equation (7) or rather (15) of the paper with Equation (d) of discussion

$-R = H \qquad K = 0.1205 \times 10^6 \qquad S = 21500$

$$\beta = -\frac{K}{H} + \frac{1}{H}\sqrt{K^2 + S^2 \times H^2} = -\frac{0.1205 \times 10^6}{H} + \frac{1}{H}\sqrt{(0.1205 \times 10^6)^2 + 21500^2 \times H^2}$$ corresponding to Equation (15)

$H \quad -R$	20	60	100	200	400	600	1000	1588
β as per above Equation (15)	16303	19586	20331	20906	21200	21300	21380	21424
β as per Equation (d)	17000	17872	18573	19789	20925	21300	21477	21499
Difference	−697	+1714	+1758	+1117	+275	0	−97	−75

is conspicuous for values of β from 18,000 to 21,000. The agreement between the two curves would be better yet, if Curve 1 would start at a residual magnetization $\beta = -\beta_0$, *e.g.*, including that amount of hysteresis which exists in the electrolytic iron under test. In the latter case H would be replaced by $-R$ and a conclusive comparison of the two pertinent Equations (**d**) and (**7**) could be made. If, then, a need for improvement of Equation (**7**) should come into evidence, it might be taken care of by adding an exponent n, possibly thus

$$R_n = -\frac{2K\beta}{(S^2 - \beta^2)^n} = -2\left(\frac{k}{S^2 - \beta^2}\right)^n \times \beta \qquad \textbf{(e)}$$

In this form, the dimensional homogeneity of the equation would be retained. Curve 6 shows the corrective effect of a coefficient $n = 0.949$ upon Curve 5. Further research work along the lines of the new theory, however, should establish a term for R which covers all cases of magnetization.

Such a revision of Equation (**7**), or one similar, should have only a limited effect upon the equation for the dissipative component D, on account of the anticipated near agreement between the curve as per Equation (**7**) and the graph of the improved term.

Since, however, the molecular friction (and hysteresis) depends very much on the material under test, it is to be expected that for different materials the D-curves will have different configurations. The many constants in Equations (**11**) to (**14**) give quite a great latitude in this respect and should accord to Equations (**11**) and (**14**) more than transitional importance.

The quantity β_h does not occur in Equations (**11**) to (**14**), because they relate D to H. β is very much in evidence in Equations (**33**), (**35**), and (**36**), and in calculations of loss in Appendix III.

The empirical character of the Equations for D is admitted, but the Curves D_1 and D_2 are rational inasmuch as they are the outgrowth of rational theory.

Section VII (Applying the Theory) was added to show first, that by reason of functional appertainment, the magnetization curve should be referred to R and not to H, and secondly, that $\tan\tau = \frac{1}{S}$, which was not known before.

Regarding Mr. Gokhale's reference to Weber's theory, according to which the magnetism is resident in the molecules, the gist of that theory will not be much altered by assuming that the molecules are ordinarily devoid of magnetism, but in magnetizable materials they can be polarized in one direction only. When magnetized to the extent of $\beta = H$ (for those molecules the polar axes of which happen to be parallel to H) and to $\beta < H$ (for those molecules the polar axes of which are not parallel to H), they tend and begin to aline their axes parallel to the field H and thereby also deflect the molecules from their original position. In so doing they encounter the friction D. At the same time the flux within them increases in accordance with their "magnetic ability." Each molecule then represents only a link in one of the many parallel chains constituting the magnetic flux of the circuit.

A further refinement of the theory will have to settle the question as to whether the polar axes are rigidly fixed to their respective molecules or whether they permit of a certain shift around them.

As the flux enters the molecules and alignment of the polar axes takes place, a reaction R is encountered. While mathematical terms are given in the paper for D and R, the writer believes himself justified in assigning the cause of those forces R and D to the thermodynamic and mechanical state of the material under test. Such conclusions are drawn from results of research published by J. A. Ewing.[4]

4. Conclusions drawn from references in Magnetic Induction in Iron and other Materials, by J. A. Ewing. Third Edition, 1900, D. Van Nostrand Co., New York.

EFFECT OF HEAT ON MAGNETICS

Page 171, Magnetization of Iron at various temperatures, Fig. 77 with $H = 0$ to 2.5. Fig. 78 $H = 0$ to 50, D decreases with increasing temperature; therefore $\frac{d\beta}{d\epsilon} > 0$ and $\frac{dR}{d\epsilon} \gtreqless 0$. For large H and β, ϵ_m is approached, hence saturation value goes down. Observe that β adds to the elongation when within a certain value. Compare Fig. 126. $H < 280$.

Page 172. Fig. 79, same case, but $H = 0.3$ = constant; $t = 0$ to 800 deg. For low temperatures: $\frac{dD}{d\epsilon} < 0$ = negative, but D remains too large. The weak $H = 0.3 < D$ cannot accomplish a parallel alignment of polar axes. R therefore remains near zero value. Above 700 deg. D is getting so small, ($D = 0$) that under the weak H, alinement of polar axes is accomplished, involving also $\frac{d\beta}{d\epsilon} > 0$ and $H = -R$, which brings about further elongation $\epsilon = F_3(\beta)$, carrying ϵ to critical value ϵ_m, thus reducing β. $\beta = H$.

Page 173. Fig. 80 $H = 4.0$ = constant. Fig. 81 $H = 45$ = const. Same process as in Fig. 79, but quantitatively different, inasmuch as the stronger field overcomes D at lower temperatures.

Page 176. Magnetization of nickel at various temperatures. Fig. 86 $H = 0$ to 80, t held constant at various values t = 13 deg., 245 deg., 284 deg., 298 deg., 308 deg.

D abates with rising temperature, which also entails increasing ϵ. As β grows larger due to the growing field intensity, D is falling off. $\epsilon = F_3(\beta)$ adds to the thermal elongation until the critical value is being approached. The greater the elongation by heat, the less elongation $\epsilon = F_3(\beta)$ is necessary to reach the critical value ϵ_m.

Page 177. Fig. 87, Field kept constant at various values H = 2.5, 10, 30, 50; while temperature varies from 0 to 310 deg. Explanations are similar to those for Fig. 79.

Page 183. Fig. 89. Bar magnet subjected to heat cycle 8-160-10 deg. Curve shows the abatement of β with separation of molecules by thermal expansion. Such separation also permits better alinement of axes of molecules, which is reflected in higher β values when the magnet cools off.

The recurrence of β and its stored magnetic energy leaves no other interpretation than that heat has been transformed into magnetism directly. This experiment should be repeated with a winding around the magnet and connected to a suitable galvanometer for checking the flow of Coulombs in and out. In that form the outfit would be an apparatus adapted to change heat into electricity.

EFFECT OF MECHANICAL STRESS UPON MAGNETS

Page 204. Fig. 98, Nickel under compression. H varies from 0 to 160; while compressive stress is held constant at various values, *e. g.*, 0, 1.9, 3.5, 6.8, 10, 13.8, 19.8 kg/mm^2. Rate of magnetization increases with compression, *e. g.*, with mutual approachment of molecules.

$$\frac{d\beta}{d(-\epsilon)} > 0 \text{ and } \frac{H_R}{(-\epsilon)} \text{ numerically larger than } \frac{D}{(-\epsilon)}.$$

Residual magnetism $+\beta_0$ increases with pressure, therefore we have $\frac{dD}{d(-\epsilon)} > 0$.

Tension applied to nickel has the opposite effect (ϵ = positive). Compare Fig. 95 on page 200.

Pages 197, 224, Villary effect:—In iron, when subjected to a weak field, a

Fig. 4 (herewith) shows the development along its axis and a cross section through a rod of magnetizable material. Certain notations are also given which are necessary for further explanations.

The outstanding feature of the aforesaid conclusions is that magnetic reaction R, magnetic friction D, and, as a sequel, β, depend very much on the relative distance between the molecules. There are various forces affecting that distance.

Briefly stated

$$R = F_1 (\epsilon, \alpha) \tag{f}$$

$$D = F_2 (\epsilon, \alpha) \tag{g}$$

In general, *e. g.*, if not counteracted otherwise,

Separation of molecules ($\Delta l = + \epsilon l$ = positive) by expansion lowers D, β, R.

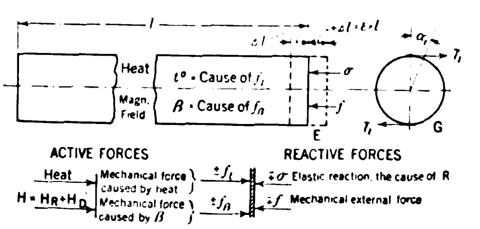

FIG. 4

Mutual approach of molecules ($\Delta l = \epsilon l$ = negative) by compression increases D, β, R, each at its own rate.

If counteraction does take place, as, for instance, when mechanical pressure opposes thermal expansion, the effect upon β depends upon

$$\frac{d D}{d \epsilon} \gtreqless \frac{d R}{d \epsilon} \text{ or } \gtreqless \frac{d \beta}{d \epsilon} \tag{h}$$

$$\frac{d D}{d \alpha} \gtreqless \frac{d R}{d \alpha} \text{ or } \gtreqless \frac{d \beta}{d \alpha} \tag{j}$$

For ϵ, a critical maximum value ϵ_m exists. When ϵ_m is exceeded, the effect is similar to that of a large air-gap or a broken magnetic chain.

To augment the above equations (**f** and **j**), the following two well-known relations should be cited:

$$\epsilon = F_3 (t_o, \beta, \sigma, f) \tag{k}$$

$$\alpha_1 = F_4 (t_o, l_1) \tag{l}$$

Observing now that $\epsilon = \sigma E$ and $\alpha_1 = \tau_1 G$, it is obvious that R and D depend on the elastic quality of the material.

It is understood, of course, that the two fundamental laws of thermodynamics also apply. They must be referred to, for instance, when explaining the change of magnetization through heat in a permanent magnet. Here they force the conclusion that heat energy is transformed into magnetic energy.

---

mechanical tension will cause β to rise; when in a strong field and put under tension, β will decrease.

This Villari effect in iron seems to indicate that in iron a negative maximum for ϵ exists. The neutral point between $(- \epsilon_m)$ and $(+ \epsilon_m)$ occurs when a certain external load is applied.

Page 243. Fig. 121. Nickel under tension and torsion. Tension alone (Curve *c c*) separates the molecules and therefore holds β low. Torsion added brings about lateral compression and a mutual approachment of molecules, and also an increase of D, the molecular friction. As soon as H has reached a value (12 in Fig. 121) to overcome this larger D, alinement of polar axes of molecules takes place "en masse," accompanied by a large increase in β. The molecules remain then in alinement for the descending branch, owing to the high value of D, and a high residual magnetism is the result.

Page 208. Fig. 102. Nickel in (successive) constant fields. H = 6.9, 21.8, 53.5, 118. Pull = 0 to 12 $\times$ 2.75 $k\,g/m\,m^2$. Separation of molecules lowers β and stored magnetic energy. Removal of tension brings back β and its energy. Case is similar to bar magnet under influence of heat, page 183.

CORRESPONDENCE

TRANSMISSION LINE SAG CALCULATIONS

To the Editor:

Referring to the paper on *Transmission Line Design*, abstracted in the A. I. E. E. JOURNAL of December 1925, p. 1352, I wish to call attention to an important omission by the author.

When there is wind pressure, the cable of a transmission line span lies in an oblique plane and not in a vertical one. It still has the shape of a catenary, and deflections in the direction of the resultant force are in the oblique plane. If one support is a distance b higher than the other, the dimension b does not lie in the oblique plane, but in a vertical one.

A new dimension $q = b/\cos \theta$ should be taken, which is the difference between the distances of the two supports from the horizontal line through the lowest part of the cable. The dimension q lies in the oblique plane. The angle θ is the angle between the oblique plane and the vertical.

This matter is not a minor correction, but it makes a large difference. For instance, in the problem with cable loaded, Table VII, of Mr. Smith's paper, b = 179 feet and the lowest point of the cable is given as 91.2 feet from the lower support, and between the two supports. If the obliqueness of the plane is allowed for, q = 197 feet and the lowest point of the extended catenary is outside of the two supports, and 34.5 feet from the lower support. The calculated sag is very materially changed.

Since the span is first calculated with a wind load, the above error affects the succeeding calculations.

It is not necessary to use an approximate calculation, as used by Mr. Smith, for the deflection from the line joining the supports, since a simple calculation depending directly on the catenary formula can be employed. See the paper on sag calculations by the writer, A. I. E. E. JOURNAL for June 1926, page 564.

H. B. DWIGHT.

To the Editor:

Mr. Dwight's letter calls attention to an important point, and one which should have been mentioned in the paper.

The reason for not taking into account the angle θ, due to the wind load, was not stated in this paper, but will be found in the previous paper on *Transmission Line Design*, by F. K. Kirsten, A. I. E. E. TRANSACTIONS, 1917. In each of these papers the maximum load at freezing temperature was considered in the vertical plane with no wind, but with the assumption that the snow accumulation might then result in a loading at least as great as the loading computed for the inclined plane with wind. Since this condition is one of the two possible maximum sag conditions, it would determine the minimum clearance to ground. This assumption, if justified, gives an added factor of safety.

If the assumption is not permissible, Mr. Dwight's suggestion must be considered. In any case a complete investigation might require the consideration of the inclined position for clearances between cables.

G. S. SMITH.

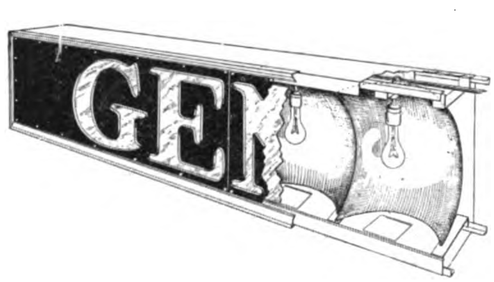
ILLUMINATION ITEMS

By Committee on Production and Application of Light

A DAYLIGHT ELECTRIC SIGN

Multiplies the Effective Hours of Electrical Advertising

Perhaps the major reason for the popularity of electrical advertising is its enormous "brightness" contrasts—its letters of fire drawn out against the dark night sky. Its use and maximum effectiveness have been confined chiefly to those hours when there is a dark night sky; and the time clocks, turning the signs off after the people are abed, are set to turn them on again only at dusk the next day. While it is true that during the evening hours advertising is most effective—when people are most receptive—yet there are daylight hours when advertisers clamor for attention. The theater, with its matinee performances, has empty seats to fill. The real-estate development, where brightest days are best for trade, finds everyone vying for attention. The shopping district stores entice the midday throngs—with as keen competition for the attention of all, those who walk or those who ride,—as at any other time. Yet, at these hours, the signs brilliant at night become mere painted messages dependent upon such secondary agencies as beauty, grace, and color to catch and hold the eye. For the filament of the incandescent lamp, although very bright, is small in size, and against the light daytime backgrounds, there is insufficient area of brightness to command attention.



DAYLIGHT SIGN

It is a simple matter, optically, to build up the area of brightness and lay images of the brilliant filament side by side so that, for example, the entire surface of a letter is given the brightness of the filament itself. Then the brilliant area is large and will attract. The traffic signal and the familiar stop signal of the motor car are examples of such building up of the area of brightness to a size at which it competes successfully with the light of day. And in the "daylight" sign, a large reflector directs an image of the filament to every point on the surface of a glass letter, giving it the brightness of a line of fire *by day*.

In obtaining this brightness, the light has been concentrated into a relatively narrow angle; hence, within this angle only is its effectiveness at a maximum. Therefore, such a sign is of greatest value when the circulation is massed within a relatively narrow viewing angle, and where people approach the sign nearly "head on" for a considerable distance. There are many such locations,—atop the marquee projecting over the sidewalk, at a dead-end street, on a highway curve,—where the new sign might well be used to give a daytime punch.

At night, the sign is effective if dimmed to a much lower brightness. The brightness used by day would fuzz and blur the letters and make them indistinguishable, even at short distances; in fact the glare would be intolerable. Dimming at night may be easily accomplished by a time clock that switches to a lower voltage transformer tap or cuts in a series resistance if in the direct-current district. Often it will be satisfactory to wire the lamps in two circuits of equal numbers and wattage, the time clock connecting the halves in series at a predetermined hour.

The use of color, preferably in the glass letter itself, improves both day and night effect. The lighter colors should be employed in order not to sacrifice the high brightness that compels attention.

The first installation of the "daylight" sign was made on Central Pier, Atlantic City. Here it is so situated and the direction of the boardwalk is such that the letters are visible to people approaching from afar and over a considerable stretch of boardwalk. It was desired to compel the attention of the passerby in an inescapable manner, even on the brightest day, and high brightness is an unfailing means to this end. Hence the "daylight" sign was used. Rippled alabaster glass, with a slightly opalescent case, smooths out streaks and striations without too great a diffusion of the concentrated beam. Back of each letter is a large, polished, parabolic reflector, with a 200-watt, Mazda C lamp so placed that the filament is at the focus of the reflector. The reflectors are turned at a slight angle so that they aim down the boardwalk approach. The necessary dimming at night is accomplished by connecting two groups of lamps of equal wattage, in series, so that each lamp in the letters receives half voltage at night.

When approaching the store from afar down the boardwalk, the effect is striking; even on the brightest days of ocean sunshine, with the white, glittering beach nearby, the more brilliant, sparkling letters of the "daylight" sign stand out beyond all surroundings and compel attention.

Pacific Coast Convention, Salt Lake City

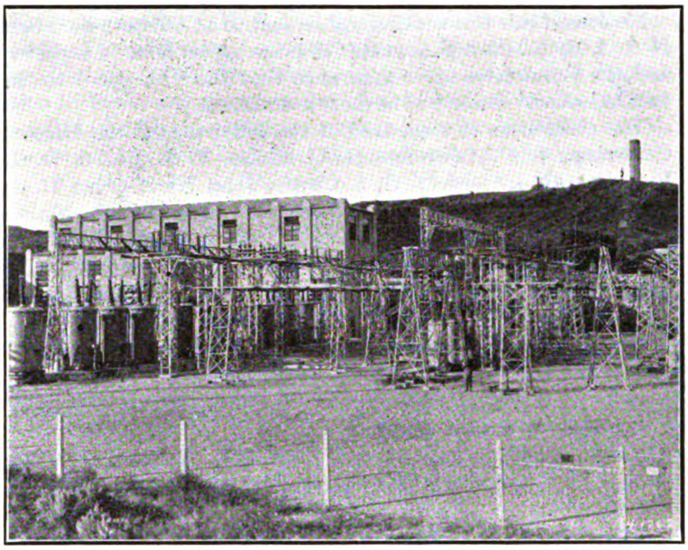
SEPTEMBER 6-9

Arrangements are being completed for the 1926 Pacific Coast Convention of the Institute which will be held in Salt Lake City, September 6, 7, 8 and 9, 1926. A special technical program is being prepared and the Convention Committee is arranging a series of events for the entertainment of those who will be in attendance. The convention meetings will be held at Hotel Utah, which will also be the headquarters for all other convention activities.

Among the wide variety of subjects covered in the technical papers will be high-voltage transmission, corona, surge recorders, vacuum switching, fire protection for generators, stability of alternators, protecting oil tanks against lightning, telephony, mining applications, education, etc. A tentative list of papers is given below.

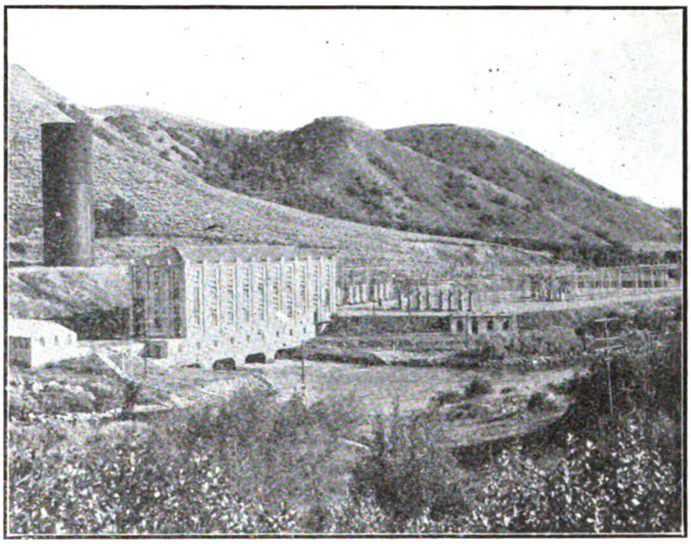
A visit to Utah at any time of the year is most delightful, and it is particularly so during the early part of September. It is planned to hold technical sessions during the forenoons, with afternoons devoted to sightseeing trips to such places as Utah Copper Company open-pit mine at Bingham, where immense tonnage of copper ore is mined with electric shovels; to the Utah Copper Company mills at Magna and Arthur, where from 30,000 to 40,000 tons of ore per day are milled and where large quantities of electric power are used; to the beautiful Saltair resort which is located on Great Salt Lake; to the numerous canyons surrounding the city, and to the many notable places of historic interest in and about Salt Lake City.

Immediately following the Convention, arrangements will be made for those interested to visit the various properties which comprise the hydroelectric development of Utah Power & Light Company. One trip of three days' duration will cover the Bear Lake-Bear River system which is one of the most highly developed hydroelectric projects in the world. Bear Lake, a natural reservoir about 30 miles long and 9 miles wide, serves as a storage and equalizing reservoir for the entire Bear River system. The



GRACE HYDROELECTRIC PLANT, UTAH POWER & LIGHT CO.

flow of Bear River, below Bear Lake, is maintained practically constant throughout the entire year for power purposes and to the great benefit of irrigation projects located along the river. At Bear Lake, a pumping plant is installed to insure water in the river even during periods of low precipitation and run-off. For those who cannot afford the three days necessary to cover the Bear Lake-Bear River System, an excursion of one day is planned



ONEIDA HYDROELECTRIC PLANT, UTAH POWER & LIGHT CO.

to the new 30,000-kw. Cutler Generating Station which will be placed in operation during the latter part of 1926 and which will be in excellent condition for inspection and study during the early part of September.

One item of interest to all electrical engineers will be the ceremony in connection with the presentation of the A. I. E. E. Edison Medal to Dr. Harris J. Ryan, Past-President of the In-

stitute and Professor of Electrical Engineering at Stanford University.

The time of the Salt Lake Convention has been planned to fit in with the convention of the Rocky Mountain Coal Mining Institute which is to be held in Glenwood Springs immediately following the Salt Lake Convention, and also the Annual Meeting of the Colorado Railway Light and Power Association, which is to be held in Colorado Springs during the week following the Salt Lake Convention.

Notices of this Convention will be sent to all Western members of A. I. E. E., during August. A large attendance is expected and the Committee gives assurance that the time spent at the Salt Lake Convention will be most profitable.

The committee is composed of the following: C. R. Higson, Chairman; P. P. Ashworth, H. G. Baker, V. L. Board, D. L. Brundige, R. J. Corfield, G. S. Covey, John Harisberger, R. A. Hopkins, C. P. Kahler, J. A. Kahn, E. A. Loew, C. A. Malinowski, J. F. Merrill, E. B. Meyer, H. T. Plumb, R. C. Powell, C. C. Pratt, Paul Ranson, L. W. Ross, John Salberg, H. H. Schoolfield, M. M. Steck, A. Vilstrup, H. B. Waters and B. C. J. Wheatlake.

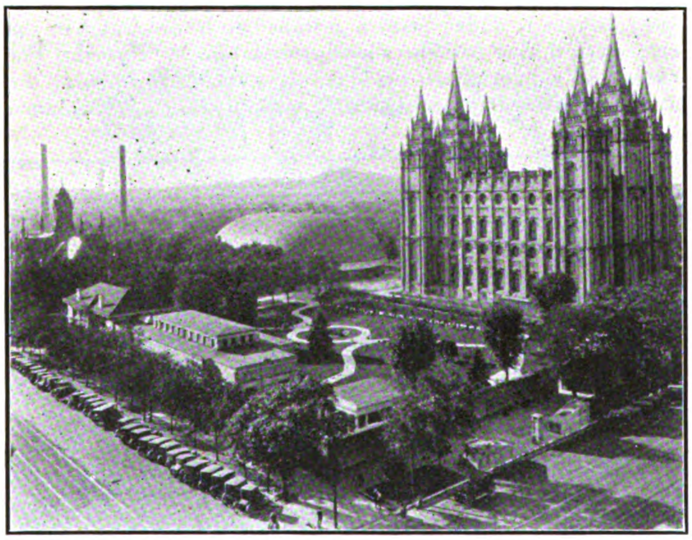
TENTATIVE LIST OF PAPERS FOR PACIFIC COAST CONVENTION

A New 220-Kv. Transmission Line, C. B. Carlson and H. Michener, Southern California Edison Co.

Effect of Unbalanced Tension in a Long-Span Transmission Line, by E. S. Healy and A. J. Wright, Electric Bond and Share Co.

110-Kv. Transmission-Line Construction of The Washington Water Power Company, by L. R. Gamble, Washington Water Power Co.

The Circle Diagram of a Transmission Network, by F. E. Terman, Stanford University.



Mormon Temple Block, Salt Lake City

The Space Charge That Surrounds a Conductor in Corona, by H. J. Ryan and J. S. Carroll, Stanford University.

Calibration of Lichtenberg Figures, by K. B. McEachron, General Electric Co.

Vacuum-Switching Experiments at California Institute of Technology, by R. W. Sorensen and H. E. Mendenhall, California Institute of Technology.

Temperature of a Contact and Related Current-Interruption Problems, by Joseph Slepian, Westinghouse Electric & Mfg. Co.

Fire Protection of A-C. Generators, by J. A. Johnson, Niagara Falls Power Co., and E. J. Burnham, General Electric Co.

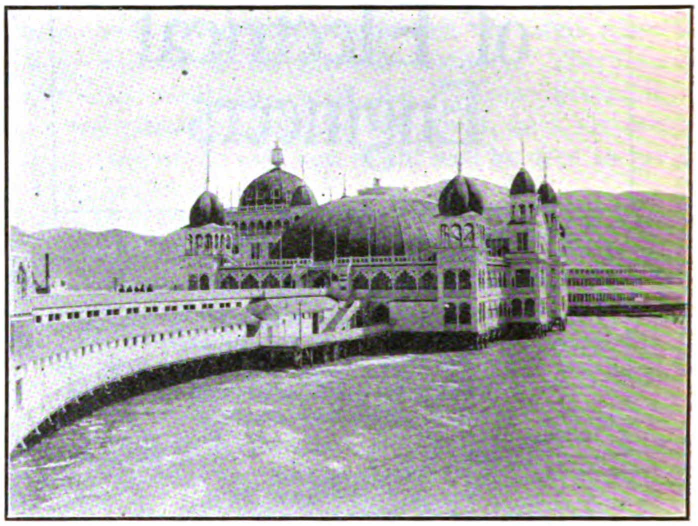
Stability Characteristics of Alternators, by O. E. Shirley, General Electric Co.

Synchronizing Power in Synchronous Machines, by H. V. Putman, Westinghouse Electric & Mfg. Co.

Protection of Oil Tanks Against Lightning, by F. W. Peek, Jr., General Electric Co.

Protecting Oil Tanks Against Lightning, by E. R. Schaeffer, Johns-Manville, Inc. (Informal presentation).

Engineering Education—Its History and Prospects, by H. H. Henline, Stanford University.



New Saltair Pavilion, Great Salt Lake

Transcontinental Telephony, by O. B. Jacobs and H. H. Nance, American Telephone and Telegraph Co.

Carrier-Current Communication on Submarine Cables, by H. W. Hitchcock, Pacific Telephone and Telegraph Co.

Controlling Insulation Difficulties in the Vicinity of Great Salt Lake, by B. F. Howard, Mountain States Telephone Co.

Electrical Practise in Lead-Silver Mines in Utah, by Leonard Wilson, Consulting Engineer.

Variable-Voltage Equipment for Electric Power Shovels, by R. W. McNeill, Westinghouse Electric & Manufacturing Co.

The White Sulphur Springs Convention

The forty-second Annual Convention of the A. I. E. E. convened at the Greenbrier Hotel, White Sulphur Springs, W. Va., President M. I. Pupin presiding. About 350 members and guests were in attendance and while it was numerically smaller than many of the previous conventions it was of the utmost technical interest because of the number of excellent papers and committee reports. The hotel and its surroundings left nothing to be desired in the way of entertainments and sports. Following the usual custom at Summer Conventions, the technical sessions were confined entirely to the mornings, leaving the balance of the day open for recreation and social purposes.

Conference of Section Delegates

The first event of the Annual Convention was the regular annual Conference of Section Delegates held under the auspices of the Sections Committee at morning and afternoon sessions on Monday, June 21.

Forty-three of the fifty-one Sections were represented by officially appointed delegates. Five of the Geographical Districts were also officially represented by their Secretaries or alternates, and there was also present a number of Counsellors of Student Branches.

The conference, which was also attended by a considerable number of officers and officers-elect and other interested members,

was presided over by Chairman Harold B. Smith of the Sections Committee. The program, which had been prepared in advance by a special committee and mailed to all the delegates, was considered in detail as follows:

1. Announcements by Professor H. B. Smith, Chairman, Sections Committee.
2. Remarks by President Pupin.
3. Remarks by President-elect Chesney.
4. Report by National Secretary Hutchinson on results of previous Sections conferences.
5. Public Relations:
   (a) Affiliation with Sections of other engineering societies and with other local organizations.
   (b) District and National speakers bureau.
   (c) The relations and service of Secticns to the community.
6. Regional Meetings.
7. Other new business.

The latter part of the conference related to organization and activities of Student Branches and was presided over by Dean C. E. Magnusson of the University of Washington, Seattle, in his capacity as Chairman of the Committee on Student Branches.

Recommendations were adopted as follows:

That a national committee be appointed to study the question of better public relations.

That the speakers bureau be strengthened or extended principally on the side of popular interpretation of scientific and engineering subjects.

That provision be made, if possible, in the budget for the coming year to pay traveling expenses for Student Branch Counsellors and incoming Student chairmen of all Branches to a District meeting each year; also to pay similar expenses for one delegate from each of the Districts to the national convention each year.

That a joint meeting of the Counsellors and incoming Student chairmen of all Branches in the two Pacific Coast Districts be held during the Pacific Coast Convention at Salt Lake City, commencing Monday, Sept. 6, 1926.

At the meeting of the Board of Directors held at the Convention on June 23, these recommendations were considered and action favorable to the objects desired was taken.

An abstract of the proceedings of the entire conference, which included discussion upon many other topics in addition to those referred to above, is being prepared and will be printed in pamphlet form and mailed to all delegates in attendance and to all officers of Sections, Branches, and the national body. Any Institute member who is interested may obtain a copy of the pamphlet without charge upon application to Institute headquarters, New York.

Tuesday, June 22

Immediately after opening the session on Tuesday morning President M. I. Pupin presented his president's address. In his address he pictured the relations of the great fundamental theories and discoveries of the science of electricity, closing with a plea for more thorough study of the marvelous properties of electricity which we are just now beginning to understand, the behavior of the electron. Dr. Pupin's address is published on page 758 of this Journal.

Following the President's address, Cummings C. Chesney, President-Elect, was introduced and he spoke briefly of his appreciation of being chosen for the presidency and of his hopes for carrying on another successful year of the Institute.

President Pupin then announced the winners of the Institute prizes for papers presented during the year 1925 and presented to the winning authors their certificates of award and cash prizes. These authors were R. W. Wieseman who won the First-Paper Prize and J. H. Cox and J. W. Legg who won the Transmission Prize. A complete account of the awards was published in the July issue of the Journal, page 685.

Following the presentation of prizes, Dr. Pupin introduced Mr. E. B. Meyer who took the chair and proceeded with the reading of the reports of the Technical Committees six of which were presented at this session. In the absence of Dr. Whitehead, Chairman, Dr. Kouwenhoven presented the report of the Research Committee. This was followed by the report of the Standards Committee which was presented by Mr. C. E. Skinner. The report of the Instruments and Measurements Committee was presented by Mr. J. R. Craighead in the absence of Chairman Knowlton, and Mr. H. P. Charlesworth followed with the report of the Committee on Communication. The final report of this session, that of the Committee on the Production and Application of light, was presented by Chairman P. S. Millar. Chairman Meyer then declared the reports open for discussion and the following members took part in the discussion which ensued:—W. E. Beaty, S. L. Gokhale, P. S. Millar, H. Goodwin, Jr., H. M. Hobart, and Dr. H. B. Dwight. At the close of the discussion the technical session adjourned until Wednesday morning.

Tuesday afternoon was devoted to golf, tennis, and other outdoor recreations as were all the afternoons during the convention. On Tuesday evening an informal reception was held in the Ball Room of the hotel. In the receiving line were President Pupin, President-Elect Chesney, and several other distinguished members of the Institute including officers past, present, and elect, together with many lady guests. Following the reception dancing was enjoyed with music by a most pleasing orchestra. Incidentally, there was dancing on every evening of the convention following the other scheduled events.

Wednesday, June 23rd

Two technical sessions were held on Wednesday morning, Session A being held in the Ball Room of the hotel. Mr. E. B. Meyer called the session to order and introduced Mr. H. M. Hobart, Chairman of the Electrical Machinery Committee, who took the chair. Three papers were presented at this session as follows:—*Synchronous Machines*, presented in part by R. E. Doherty and continued by C. A. Nickle. The discussion of this paper followed immediately on its presentation and the following men participated: C. A. Adams, P. L. Alger, M. I. Pupin, R. W. Wieseman, R. D. Evans, and H. B. Dwight, with closure by R. E. Doherty. The next paper on the program, *Graphical Solution of A-C. Circuits*, by F. W. Lee, was presented by Dr. Kouwenhoven in the absence of the author. Discussion followed by M. I. Pupin, W. P. Dobson, C. A. Adams, D. C. Prince, Harold Pender, R. E. Doherty, and C. W. Bates. The title of the third paper on the program was *Multiplex Windings for D-C Machines* and was written by C. C. Nelson. As the author was not present the paper was read by Mr. H. B. Dwight and was discussed by W. B. Kouwenhoven, H. B. Dwight, J. L. Burnham, and C. A. Adams.

Session B on Wednesday morning was held in the Tudor Room of the hotel and was presided over by Mr. F. L. Hunt. The first paper to be presented was entitled *Remotely Controlled Substations* and was abstracted by its author, W. C. Blackwood. This was discussed by C. M. Gilt, F. B. Johnson, C. Lichtenberg, E. K. Huntington, G. O. Brown, with closure by Mr. Blackwood. The next paper of the session was entitled *The High-Speed Circuit Breaker in Railway Feeder Networks*, by J. W. McNairy who presented it in abstract, following which a written discussion by R. J. Wensley was presented by title. Verbal discussion followed by J. J. Linebaugh and C. Lichtenberg. The final paper was by Alfred Bredenberg, Jr., and was entitled *Regenerative Braking for D-C Locomotives*. This was abstracted by the author. As there was no discussion of this paper the meeting adjourned.

Two of the entertainment features which the ladies particularly enjoyed were the auto drive on Wednesday afternoon and the card tournaments on Thursday evening.

In the drive on Wednesday, automobiles took a large party through some of the most beautiful mountain and valley scenery, a stop being made at Lewiston for tea.

On Thursday evening both bridge and hearts were played by a large number of ladies and men. The winner at each table received a salad bowl as a prize.

Standardizing Organizations Discussed

On Wednesday evening the relations between the Institute, the American Engineering Council and two major standardizing organizations were outlined by three able speakers. Dr. C. H. Sharp, described the activities of the International Electrotechnical Commission. He mentioned the agreements which have been reached among various nations and suggested the possible formation of an international standards association.

L. W. Wallace, executive secretary of the American Engineering Council, told of the work of that organization, particularly in advocating congressional acts dealing with the Patent Office, Mapping, Muscle Shoals, Salaries of Federal Judges and Radio Broadcasting. The Council has prepared a number of reports on important questions including waste in industry, the twelve-hour shift, commercial aviation and accidents and production.

C. E. Skinner, chairman of the American Engineering Standards Committee, told of the objects and work of that body. He mentioned the rules of procedure for making standards which have been prepared and pointed out the mutual benefits which would result if all standards-making bodies follow these rules as a guide.

The regular meeting of the Board of Directors was held at two-thirty Wednesday afternoon. A resumé of the business transacted by the Board will be found elsewhere in this issue.

Thursday, June 24th

The session on Thursday morning was presided over by Progessor H. B. Smith and like the Tuesday morning session was devoted entirely to the presentation of Technical Committee reports. All of the reports were presented in abstract and were as follows: Report of the Committee on Power Transmission and Distribution, P. H. Thomas, Chairman, presented by P. H. Chase, Vice-Chairman; Report of the Committee on Protective Devices, E. C. Stone, Chairman, presented by F. L. Hunt, Vice-Chairman; Report of the Committee on Applications to Iron and Steel Production, F. B. Crosby, Chairman, presented by A. G. Pierce; Report of the Committee on General Power Application, A. M. MacCutcheon, Chairman, presented by Mr. MacCutcheon; Report of the Committee on Applications to Mining Work, F. L. Stone, Chairman, abstracted by H. A. Winne; Report of the Committee on Applications to Marine Work, L. C. Brooks, Chairman, presented by A. G. Pierce; Report of the Committee on Electrochemistry and Electrometallurgy, G. W. Vinal, Chairman, abstracted by Mr. Vinal; and the Report of the Committee on Power Generation, V. E. Alden, Chairman, presented by Mr. Alden. An extended discussion followed which was participated in by W. S. Lee, W. A. Del Mar, R. D. Evans, H. R. Summerhayes, M. I. Pupin, C. A. Nickle, H. M. Hobart, and R. N. Conwell.

Friday, June 25th

On Friday morning the last two technical sessions of the Convention were held in parallel. Session A was under the chairmanship of W. A. Del Mar and the first paper to be presented was *The Mechanism of Breakdown of Dielectrics*, by P. H. Hoover. This was discussed by W. F. Davidson, P. L. Alger, R. W. Wieseman, and in a written discussion by R. W. Atkinson read by E. Kirschner. The second paper presented in Session A was by D. C. Prince and was entitled *Mercury Arc Rectifiers*. The paper was abstracted by Mr. Prince and discussed by C. P. Osborne, A. H. Mittag, J. A. Cook, D. C. Prince, W. A. Hildebrand, W. F. Davidson, and R. D. Evans, with closure by A. V. Mershon.

Session B on Friday morning was called to order by Mr. L. W. Morrow who called on Mr. Gokhale to abstract his paper on *Law of Magnetization*. It was discussed by J. R. Craighead, H. Lippelt (by letter), W. L. Upson, and J. E. Jackson, with closure by Mr. Gokhale. The next paper was entitled *Surface Heat Transfer in Electric Machines with Forced Air Flow*, and was by G. E. Luke who presented it in abstract. This was discussed by J. L. Burnham with closure by G. E. Luke. The final paper of the session was on *General Theory of the Auto-Transformer* which was presented by the author, W. L. Upson. This was discussed by J. R. Craighead with closure by Mr. Upson. The session then adjourned.

The Golf Tournament

A great many of the men at the meeting participated in the golf tournament and in addition there was a ladies' putting contest. The golf tournament, which was played for the Mershon Trophy, was very closly contested. After all other contestants had been eliminated, Friday afternoon brought a match between the two remaining players, H. C. Don Carlos and W. P. Dobson. Their match however resulted in a tie. Therefore as both of these gentlemen reside in Toronto the committee decided that they should play off the match later on a Toronto course. Subsequently this was done and this time Mr. Don Carlos was victorious by a score of four up and three to go. Accordingly his name will be added to the eleven other names already on the Mershon Cup. He will not have permanent possession of the cup as it is required that a contestant win this annual tournament twice before he may keep the cup. He received, however, as a permanent prize another handsome cup. Mr. Dobson as runner-up also received a cup.

The winners of the other features were as follows: N. M. Garland had the low gross score (79). Farley Osgood had the low net score (63 with 21 handicap). W. S. Lee won the final of the second flight, and R. F. Gheen was runner-up. P. M. Lincoln won the final of the third flight, while W. B. Kirke was the runner-up.

The ladies' putting contest was won by Mrs. N. M. Garland, the prize consisting of a silver vase, and Mrs. H. W. Young won a bronze bowl as second prize.

Tennis Tournaments

Tennis tournaments, both singles and doubles, were played. L. B. Chubbuck won the singles tournament and H. B. Dwight was runner-up. For this Mr. Chubbuck's name will be placed on the Mershon Tennis Trophy and he received a silver cup as a permanent prize. For permanent possession of the Mershon Cup the same player must win the tournament twice.

The doubles tournament was won by H. R. Summerhayes and E. H. Hubert. The runners-up were P. M. Alger and D. C. Prince.

The annual Convention Committee, the efficient management of which insured a most successful convention, consisted of the following: Farley Osgood, Chairman, W. R. Collier, W. S. Lee, E. B. Meyer, W. E. Mitchell, A. M. Schoen, H. B. Smith.

Twentieth Anniversary of Illuminating Engineers

Marking the founding of the Society in 1906, the Twentieth Anniversary Convention of the Illuminating Engineering Society will be held at Spring Lake, New Jersey, September 7th to 10th inclusive, when the great advances and developments which have been made during the past 20 years in this special field of Engineering activity will be fittingly observed. A program of diversified and comprehensive papers on subjects of great practical interest has been arranged by the Committee in charge. One special feature of the program particularly appropriate at this time will be a session devoted to developments in the art of illumination which have taken place during this twenty-year period. Another session will be of interest to central-station

lighting men and devoted to the presentation and discussion of the Lighting Sales Manual, prepared by a joint committee of the Illuminating Engineering Society and the National Electric Light Association. The manual outlines methods found most efficient by some of the leading illuminating engineers of the country in promoting good lighting by central stations. Central-station lighting men from the leading public utilities are to be invited to discuss the manual and promote its adoption and use.

The entertainment features of the program have not been overlooked, and the hotel, with its surroundings admirably adapted to provide the recreational features, will repeat the success of previous meetings; golf, bathing in ocean or pool, tennis, country roads to attract the lover of horseback riding, boulevards for the motorist, broad porches overlooking the ocean are but a few of the many attractions. Special features of entertainment will be provided for the ladies.

World Power Conference Program and Appointments

Topics for discussion at the sectional meeting of the World Power Conference to be held in Basle, Switzerland, August 31 to September 12, 1926, in which the American Committee of the conference will participate, include the utilization of water power, inland navigation, exchange of electrical energy between countries, electricity in agriculture and railway electrification.

This is shown in the technical program of the sectional meeting of the World Power Conference, copies of which have been received by O. C. Merrill, executive secretary of the Federal Power Commission, Washington, D. C., Member of the Institute and general chairman of the American Committee.

Beside Mr. Merrill according to a recent announcement the following American engineers will attend the World Power Conference. Prof. A. E. Kennelly and Prof. Harry E. Clifford, of the Department of Electrical Engineering, Harvard University; John W. Lieb, vice-president, New York Edison Company; Louis Marburg, of Marburg Brothers, Inc.; O. G. Thurlow, chief engineer, Alabama Power Company; Hugh L. Cooper, Consulting Engineer; and David B. Rushmore, formerly consulting engineer, General Electric Company.

Following are some of the papers to be presented by the American delegation Committee:

The Economic Relation Between Electrical Energy Produced Hydraulically and Electrical Energy Produced Thermally: Conditions Under Which the Two Systems Can Work Together to Advantage, by W. E. Mitchell, Vice-President, Alabama Power Company, Birmingham, Ala.

Electricity in Agriculture, by Dr. E. A. White, Director, Committee on the Relation of Electricity to Agriculture, Chicago, Illinois.

Railway Electrification, by W. S. Murray, Consulting Engineer, New York City.

National Aspects of the Study of Water Resources, by Nathan C. Grover and John C. Hoyt, Geological Survey, Department of the Interior.

Utilization of Water Power, and Inland Navigation, by Colonel Hugh L. Cooper, Consulting Engineer, New York City.

Exchange of Electrical Energy Between Countries, by Colonel William Kelly, Director of Engineering, National Electric Light Association (formerly Chief Engineer, Federal Power Commission).

Up to the present time, twenty-nine countries have agreed to take part in the conference and sixty-five reports have been received. A complete list of the authors and titles of the reports, together with the conditions governing them, may be obtained from the Secretary of the World Power Conference, (World Power Conference, Basle). At the close of the conference, a full report, including the discussions, will be published.

The opening meeting of the conference will be held on Tuesday, August 31st. Tuesday afternoon and Wednesday (Sept. 1st) will be given over to the reports on utilization of hydraulic power and inland navigation. Thursday and Friday, September 2nd and 3rd, will be occupied with discussions on railway electrification and electricity in agriculture.

On Saturday and Sunday (Sept. 4th and 5th), a special train, generously provided by the Swiss Federal Railways, will take the party to the Gotthard to inspect the electrification works.

Monday and Tuesday, September 6th and 7th, will be given up to the reports on hydroelectric and thermal power, and the exchange of power between countries. The closing meeting will be held on Wednesday, September 8th.

Following the conference, a number of visits have been arranged to industrial establishments September 8th and 9th, and from the 10th to the 13th, there will be two somewhat longer excursions which will enable the visitors to see something of the wonderful scenery of Switzerland. One will be to the Engadine, with Buchs as the objective, whence opportunities will be offered for further excursions to Austria, Germany, Czecho-Slovakia, Hungary, Norway and Sweden. These will be organized by the National Committees of the countries concerned. The other excursion will include the Bernese Oberland and the West of Switzerland with the possibility of extended trips to Italy, France, Belgium and Holland.

Further details regarding the program of the conference and the excursions may be obtained from the Secretary of the World Power Conference.

A. I. E. E. Directors' Meeting

The regular meeting of the Board of Directors of the American Institute of Electrical Engineers was held at the Greenbrier Hotel, White Sulphur Springs, W. Va., on Wednesday, June 23, 1926, during the Annual Convention of the Institute.

There were present: President M. I. Pupin, New York; Past-President Farley Osgood, New York; Vice-Presidents Harold B. Smith, Worcester, Mass.; Edward Bennett, Madison, Wis.; Arthur G. Pierce, Cleveland; W. P. Dobson, Toronto; Managers H. M. Hobart, Schenectady; G. L. Knight, Brooklyn, N. Y.; J. M. Bryant, Austin, Tex.; M. M. Fowler, Chicago; H. A. Kidder, New York; H. P. Charlesworth, New York; National Secretary F. L. Hutchinson, New York. Also, by invitation, C. H. Sharp, C. E. Skinner (representatives of Standards Committee), and G. O. Brown (representing Vice-President-Elect A. E. Bettis).

The minutes of the Directors' meeting of May 21, 1926, were approved as previously circulated.

A report of a meeting of the Board of Examiners held June 11, was presented and the actions taken at that meeting were approved. Upon the recommendation of the Board of Examiners, the following actions were taken upon pending applications: 61 Students were ordered enrolled; 342 applicants were elected to the grade of Associate; 11 applicants were elected to the grade of Member; 38 applicants were transferred to the grade of Member; 9 applicants were transferred to the grade of Fellow.

The Board ratified the action of the Finance Committee in approving for payment, monthly bills amounting to $28,743.86.

The Finance Committee called attention to the fact that, under the by-laws, traveling expenses are paid for Section delegates to the Annual Convention covering actual transportation expenses both ways, including Pullman and meals enroute, but that other traveling expenses have been authorized on the basis of ten cents per mile one way. The committee recommended that all traveling expenses be placed upon the uniform basis of ten cents per mile one way from the place of residence to the meeting place, excepting that in the case of members, who are appointed to represent the Institute upon special occasions, actual traveling and hotel expenses shall be paid, upon application. The Board

voted that the recommendation be adopted, and directed that Section 46 of the Institute By-laws be amended accordingly.

The Finance Committee called attention to Section 22 of the Institute constitution, which provides that "upon application, the Board of Directors shall exempt from future annual dues, any Fellow, Member, or Associate who has paid dues for thirty-five years, or who shall have reached the age of seventy after having paid dues for thirty years," and recommended that such members be designated "Members for Life" (in distinction from the present "Life Membership" list, which includes those who commute their future dues by payment of a single sum as provided in the by-laws). The Board voted that applications for permanent exemption from further payment of dues received hereafter under Section 22 of the constitution, be referred to the Finance Committee, with power; also that all members so exempted in future shall be designated in the Institute records as "Members for Life."

The Committee on Coordination of Institute Activities reported that it is desirable to schedule all important meetings of the Institute much further in advance than heretofore, some of the reasons being the desirability of reserving the necessary meeting rooms, hotel accommodations, etc., and of avoiding conflicts with the meeting dates of other organizations as far as possible. Upon the recommendation of the committee, the following schedule of meetings was approved (the first two meetings had previously been approved by the Board): Pacific Coast Convention, Salt Lake City, September 6-9, 1926; New York Regional Meeting, November 11-12, 1926; Midwinter Convention, New York City, beginning Monday, February 7, 1927; North Eastern District Regional Meeting, April or May 1927 (place to be determined later—Pittsfield, Mass., and other places under consideration); Annual Convention, Detroit Section territory, beginning Monday, June 20, 1927; Pacific Coast Convention 1927 (place and date to be decided upon later by the Pacific Coast membership).

The Committee on Coordination of Institute Activities also recommended that, inasmuch as several annual conventions are now held, the use of the expression "Annual Convention of the Institute" be discontinued and that the three principal annual national conventions be designated as follows: "Winter Convention," "Summer Convention," and "Pacific Coast Convention;" also that the serial numbers applying to the Annual Conventions as held heretofore be continued and applied to the Summer Convention only. This recommendation was approved by the Board.

Other matters of importance were discussed, reference to which may be found in this and future issues of the JOURNAL.

Prizes for Papers Awarded in Northeastern District

Prizes for papers presented during 1925, in the Northeastern District of the Institute, have been awarded by the Prize Committee of that District.

The committee awarded the Best-Paper Prize to K. B. McEachron and E. J. Wade for their paper *Studies of Time Lag of Needle Gaps.* Each author received a certificate of award, and a cash prize of $25 was divided between them.

Honorable mention was awarded to I. F. Kinnard and H. T. Faus for their paper *Temperature Errors in Induction Watthour Meters*, and to R. F. Franklin, for his paper *Short-Circuit Currents of Synchronous Machines.*

The First-Paper Prize for the District was awarded jointly to R. W. Wieseman, for his paper *A Two-Speed Salient-Pole Synchronous Motor*, and C. A. Nickle, for his paper *An Electro-Mechanical Problem Analyzer.* A certificate was presented to each author and a $25 cash prize was divided between them.

Honorable mention was given to F. M. Clark, for his paper *Effect of Repeated Voltage Application on Fibrous Insulation*, and to E. J. Burnham, for his paper *Overvoltages on Transmission Systems Due to Dropping of Load.*

The District Prize Committee consisted of P. M. Lincoln, chairman; A. C. Stevens, secretary; F. J. Adams, A. E. Knowlton and H. W. Tobey.

Saskatchewan Section Holds Meeting in a Camp

A three-day meeting in a tent camp was held by the Saskatchewan Section on July 8, 9 and 10, at Estevan, Saskatchewan. Twenty-nine tents were erected to accommodate the one hundred members of the Section and the invited Saskatchewan Branches of the Engineering Institute of Canada and the Canadian Institute of Mining and Metallurgy.

Meetings were held in a large marquee erected for the purpose. The following papers were read:

Electrical Development of Southern Saskatchewan, by S. R. Parker.

Industrial Development of Southern Saskatchewan, by W. H. Greene.

Preservative Treatment of Wood, by R. D. Prettie.

Addresses were delivered by Dr. Chas. Cansell, Deputy Minister of Mines, Ottawa; Professor Hall, of the University of Manitoba; Professor Worcester, of the University of Saskatchewan; and Mr. Thorn, Chief of the Natural-Resources Branch of the Canadian Pacific Railway, Calgary.

On Thursday, July 8th, visitors were the guests of the Town of Estevan, at a complimentary banquet.

The large attendance was recorded in spite of heavy rains the day before the meeting opened, which necessitated many of the members driving through mud for distances of two and three hundred miles. One much appreciated feature of the meeting was the low cost of sleeping accommodations, for which each adult was charged two dollars, while children were taken care of without charge. The novelty of camping out was greatly enjoyed and all voted the meeting a great success.

Armour Institute and Northwestern University to Unite

On June 30, Armour Institute of Technology, at Chicago, brought to a successful close a campaign for raising a million dollars as a preliminary move in its affiliation with Northwestern University. Of the million dollars, the alumni subscribed more than one-third, the balance being made up of donations from members of the Armour family, a citizen of Chicago interested in engineering, and several public utility corporations.

A further call for $10,000,000, for endowment and buildings to be erected on the Evanston Campus of Northwestern University and on the McKinlock Campus at Chicago Avenue and the Lake, is being undertaken under the leadership of Samuel Insull, Chairman of the Joint Trustees Committee. The arrangement between the two institutions allows a five-year period in which they shall jointly attempt to raise the capital fund.

A Request for Decision on Radio Law

The failure of Congress to complete radio regulation and the confusing decisions rendered by the Courts on radio laws of 1912 have led the Department of Commerce to request an opinion from the Attorney General on the whole situation of Departmental authority. The most important feature of the matter is in respect to the right to assign, enforce or deny the use of specific wavelengths to individual stations,—the key to the whole regulation.

Since 1923 the Department has been making such assignments in accordance with decision of the Court of Appeals, District of Columbia, rendered during that year, on the assumption that,

by the law of 1912, they were under duty to make such assignments to prevent interference. Recent decision of the Chicago Court, however, cast doubt on this authority. The Attorney General now likewise disagrees with the construction of the Court of Appeals, advising that while each applicant must designate a definite wavelength, outside the band between 600 and 1600 meters, it is still his prerogative to use other wavelengths at will. Persons desiring to construct stations must determine for themselves whether or not there are specific wavelengths available for their use without being subject to interference from other stations. They must simply proceed at their own risk.

University of Pennsylvania Creates New Course

The creation of a new graduate course to prepare men for engineering research or for teaching and which will lead to the degree of Master of Science in Electrical Engineering has been announced by Dr. Harold Pender, Dean of the Moore School of Electrical Engineering of the University of Pennsylvania and Fellow of the Institute.

At the same time, Dean Pender announced that four graduate fellowships, each of which carries with it free tuition and a cash stipend of $500, have been made available to encourage students who are properly qualified to add a fifth year to their university training. Applications for the fellowships may be made to the Dean of the Moore School.

The course will begin with the academic year of 1926-27, and will include the following subjects; introduction to mathematical physics, advanced mathematics for engineers, advanced electric-circuit theory, electron theory and its engineering applications, and a thesis.

Each graduate student will be required to complete an independent and original investigation in some field of electrical engineering. The student will be encouraged to select his own problem and must submit monthly reports on the progress of his investigation.

Applicant must have completed with credit an undergraduate course in electrical engineering substantially equivalent to that given in the Moore School.

A Uniform Electrical Ordinance

A uniform electrical ordinance has been prepared by the Electrical Manufacturers Council, providing that work done in accordance with the regulations as laid down in the two national codes shall be prima facie evidence that it is in conformity with the most approved methods of construction for safety to life and property. As the number of municipalities adopting this ordinance increases, the inspection situation will become simplified accordingly.

This ordinance provides, also, for the adoption of modifications in the codes as they are made, so that it may be possible to keep in step with the progress of the codes without the necessity of a detailed local study of each revision. The only subjects in need of local restudying from time to time are the special local rulings which can either be issued separately in bulletin form or can constitute separate articles of the local ordinance adopting the codes as its basic article.

The inspector has played an important part in formulation and revision. He has eliminated from them much that was undesirable and is constantly suggesting changes to cover either old, unnoticed or new conditions.

There are two ways in which he may assist—as an individual or as a member of an inspectors' organization. One of the most important services to be brought about is the general use of national codes of American standards.

The Committees in charge of the revision of the codes welcome constructive suggestions and criticisms from inspectors as individuals facilitate the acquisition of this knowledge, the National Fire Protection Association, sponsor for the National Electric (Fire) Code, has appointed a field secretary whose business is to keep in personal touch with inspectors and present their views to the Electrical Committee of the Association.

Power Show Reflects Tremendous Advances

Contemplation of the rapidly increasing demand for mechanical power by the industries and homes of the United States reveals the secret for its success and leadership as an industrial and commercial nation. Greater and more economical production at a smaller expenditure of human energy is the reason for its supremacy. Mechanical power as utilized in the automobile and tractor, in the locomotive and steamboat, and as derived from the electric motor in the factory and home, lies at the root of the growth of the country and of the increase in the physical and spiritual well-being of its people. The tremendous advances in the art of generating power to meet the demand are emphasized by the recent announcement by an eastern public utility of the award of a contract for a steam turbine to generate 160,000 kilowatts or more than 210,000 horse power. This gigantic machine is 60 per cent larger than the largest turbine previously constructed. Compared with the turbines of ten years ago, it is considered a miracle of the engineering world. A more interesting contrast is called to mind by the opening of the Exposition in Philadelphia fifty years ago when, after some speech-making, President Grant and the Emperor of Brazil started the giant Corliss Engine, generating 1400 horse power, weighing 700 tons, and requiring sixty-five freight cars to deliver in Philadelphia.

To reflect these enormous strides in the mechanical arts and to make them available to the engineering and industrial public is the important function of the National Exposition of Power and Mechanical Engineering which is held annually in the Grand Central Palace in New York City. The Fifth Exposition will be held from December 6 through 11, 1926, and will fill four floors of the Palace with showings of all types of power and heat generating, distributing, and using equipment. It will include refrigerating, heating and ventilating machinery and machine tools and power transmission devices, in addition to the usual important exhibits of power plant apparatus. Over 450 exhibitors will provide a well-balanced exposition that will have something novel and important for every mechanical engineer and industrial executive.

The exposition is under the management of Fred W. Payne and Charles F. Roth with offices in the Grand Central Palace.

Westinghouse Awards Educational Scholarships

Four scholarships each of which provides for payment of $500 a year to be applied toward an engineering education have been awarded by the Westinghouse Electric and Manufacturing Company. The winners of the awards, based on the 1926 competitive examination given by the Educational Department, are Robert R. Lockwood, an employe of the company and student in the night school of Carnegie Institute of Technology; William J. Morlock, a graduate of the McKeesport (Pa.) High School; Frank M. Redman, graduate of Grant High School, Portland, Oregon; and Harry W. Thiemecke, company employe and student at Carnegie Institute of Technology.

Fifty-two applicants competed for the scholarships which were established by the Westinghouse company as a memorial to those of its employes who served in the World War.

Employes, or sons of employes, are eligible for the examinations, which are held annually. The awards are granted for one year only but will be continued for the full engineering course if the student meets the academic and other standards

of his school. Since the fund was established at the close of the war, 32 Westinghouse Scholarships have been awarded.

Mr. Lockwood will take up Electrical Engineering at Carnegie Institute of Technology, Mr. Morlock at Ohio State University, and Mr. Redman at Leland Stanford University. Mr. Thiemecke will take Ceramic Engineering at Ohio State University.

The committee in charge of the awards consists of L. A. Osborne, chairman, and Walter Cary, vice presidents of the company, and T. P. Gaylord, Acting Vice President.

AMERICAN ENGINEERING COUNCIL

SEEKS SOLUTION OF BROADCASTING PROBLEM

A public service solution of the broadcasting problem is sought by the American Engineering Council, according to announcement made by its president, Dexter S. Kimball, of Cornell University.

A committee of investigation will be appointed to examine the whole situation in an attempt to obviate the "radio chaos" which may affect some 20,000,000 listeners. Dean Kimball asserts that many of the problems are of an engineering nature and that he believes a careful study of them, in an unbiased, broad-minded, and comprehensive way by a special committee chosen for that purpose, will be productive of results beneficial and of convincing form. He states that there are now 540 broadcasting stations, at least 200 of which are giving regular programs of considerable interest to substantial audiences, and approximately 600 additional applicants still remain, to whom broadcasting licenses have not been granted by the Department of Commerce.

PROPOSED LEGISLATION FOR DIVISION OF SAFETY

The House Committee on Labor, on May 21st, 1926, decided to report favorably upon a bill presented by Representative Rathbone, of Illinois, proposing legislation for the creation of a Division of Safety in the Department of Labor.

The duties of such Division will be to collect statistics on industrial situations involving jeopardized safety, with special reference to cause, effect and occupational distribution, and present them to the Department together with coincident recommendations of plans for labor safety and devices for various application to this end.

The bill provides for the cooperation of all other Governmental Departments interested in this work, and a museum exhibit of protective devices for the prevention and control of industrial disease, both mechanical and physical.

RECOMMENDATIONS FOR ORDNANCE RESERVE COMMISSIONS

As a result of the efforts of American Engineering Council and other Engineering Organizations to assist the Ordnance Department in recruiting the Reserve Corps, many recommendations have been received from the field men placed in charge of this work. Local leaders in the engineering profession in many cases have submitted names of prominent engineers who are capable and willing to fill these commissions. These recommendations have been submitted to the Director of Commissioned Personnel in the Office of the Chief of Ordnance who in turn, will submit them to the district officers of the Engineer Corps. The men will then be interviewed preparatory to choosing those best suited for appointment.

Effect of Bus Transportation on Railroads

All common carriers using motor bus transportation have been called upon by the Interstate Commerce Commission to give complete information regarding the operation of their motor bus and motor truck lines including, as far as possible, the effect on railroad traffic or competing motor transportation.

A series of dates have been set for hearings during July, August and September, covering 14 cities. These hearings will be conducted by Commissioners Esch and Aitchison and Examiner Flynn.

International Mid-Continent Engineering Convention

The Minnesota Federation of Architectural and Engineering Societies will hold an International Mid-Continent Engineering Convention in Duluth and on the Mesabi Iron Range, August 12th, 13th and 14th. The program will include papers descriptive of the great iron-mining and transportation industries in northern Minnesota and Wisconsin and visits to mines, docks and mills. There will be a banquet with speakers of national repute, and other entertainment. Special provision will be made for entertaining the ladies. The architects and engineers of Canada and this country are cordially invited. Inquiries should be addressed to W. H. Woodbury, 510 Wolvin Bldg., Duluth, Minn.

The Federation which is planning the convention is composed of a number of engineering and architectural organizations, including the Minnesota Section of the American Institute of Electrical Engineers.

Howard N. Potts Medal Award

Dr. W. D. Coolidge, assistant director of the research laboratory of the General Electric Company and inventor of an X-ray tube which bears his name and which is universally used in hospitals and laboratories, has been awarded the Howard N. Potts gold medal for 1926 by the Franklin Institute of Philadelphia.

The medal, to be formally presented by the institute on October 20, is "in consideration of the originality and ingenuity shown in the development of a vacuum tube that has simplified and revolutionized the production of X-rays," according to the Institute's citation.

In accepting the medal, Dr. Coolidge will present a paper on his new and powerful cathode-ray tube.

PERSONAL MENTION

B. M. Horter, who had been connected with the Philadelphia office of the Cutler-Hammer Mfg. Co., has been appointed manager of that company's Boston office.

Ralph B. Stewart, Associate of the Institute and former member of the United States Patent Office, has opened his own offices in Washington, D. C., as Patent Attorney.

William H. Cahoon, formerly of Ford, Bacon and Davis, Inc., Engineers, is now connected with George F. Hardy, Consulting Engineer, New York City, as electrical engineer.

B. Lester, Assistant to the Industrial Sales Manager of the Westinghouse Electric and Manufacturing Company, and Member of the Institute, recently removed from East Pittsburgh to New York.

David Hall, a Fellow of the Institute, who has been associated with the Westinghouse Electric and Manufacturing Company at East Pittsburgh, Pa., as power engineer, has been transferred to Los Angeles, as manager of their engineering division for that district.

F. F. Elznic, previously with Charles Cory & Sons Co., Inc., of this city, has just become president of the Acorn Manufacturing Co. and is doing much to increase the capacity of the organization. The Vice President and General Manager is Mr. S. N. Nead, Jr.

B. Tikhonovitch, connected with the Engineering Department of the New York Edison Company, was recently transferred to the Electrical Engineering Department as assistant to the designing engineer. Mr. Tikhonovitch has served on

the Generating Station Committee and other Committees of the Institute.

JOSEPH N. MAHONEY, Fellow of the Institute and actively prominent in the electrical field since 1898, has formed new affiliations with the American Brown Boveri Electric Corporation of New York City as their manager of engineering. This change was made by Mr. Mahoney last month, prior to which time he had been rendering valuable service as Sales Manager and consulting engineer of the Sperry Gyroscope Company. His scientific labors have embraced work in almost every branch of the engineering profession, for beside joining the Institute in 1917, he is as well an active member of the American Society of Civil Engineers, The American Society of Mechanical Engineers, the American Institute of Mining Engineers, the American Electro-Chemical Society, the Society of Automotive Engineers, and the Brooklyn Chamber of Commerce.

Addresses Wanted

A list of members whose mail has been returned by the postal authorities is given below, together with the addresses as they now appear on the Institute records. Any member knowing the present address of any of these members is requested to communicate with the Secretary at 33 West 39th St., New York, N. Y.

All members are urged to notify the Institute headquarters promptly of any change in mailing or business address, thus relieving the member of needless annoyance and also assuring the prompt delivery of Institute mail, the accuracy of our mailing records, and the elimination of unnecessary expense for postage and clerical work,

1.—Bernard Bider, 4560 N. Central Park. Ave., Chicago, Ill.
2.—A. F. Buckley, 211 Sherman Ave., New York, N. Y.
3.—E. W. Hoover, 1482 E. Stark St., Portland, Ore.
4.—M. E. Johnson, 133 Ardsley Road, Schenectady, N. Y.
5.—H. A. Katz, 1402 Monadnock Bldg., Chicago, Ill.
6.—D. F. McConnell, 402 N. Highland Ave., Pittsburgh, Pa.
7.—J. F. Wessel, U. G. & E. E. Corp., 111 Broadway, New York, N. Y.

Obituary

Charles E. Scribner, a Fellow of the Institute since 1913, and one of its vice-presidents from 1913 to 1915, died at his summer home in Jericho, Vt., June 25, 1926. Mr. Scribner, who was 68 years of age, had been actively engaged in work in the electrical field for more than forty years.

Born in New York, he removed very early to Toledo, Ohio, where he was educated in the public schools. In 1876 he went to Chicago, taking with him his first invention—an automatic telegraph repeater. A year later he obtained employment with the Western Electric Manufacturing Company, the name of which was afterward changed to the Western Electric Company. Later he became chief engineer of the company. For 22 years he served in that capacity, at the end of which time he was made consulting engineer for the same concern and remained with them until his retirement from active business.

Mr. Scribner was a well-known electrical inventor, having taken out almost 500 patents during the course of his active service. After the death of Steinmetz, he was credited with holding more patents in the electrical field than any other man save his friend, Thomas A. Edison, who said of him:

"I had the greatest admiration for Mr. Scribner's imaginative power and his ability to visualize and anticipate in minute detail the requirements of the vast technique that has been gradually built up in the electrical industry. Mr. Scribner was the most industrious inventor I ever have known. He was apparently indefatigable and his imagination seemed to be boundless."

Most of his inventions related to telephone apparatus. The first multiple switchboards to be used commercially on a large scale were of Mr. Scribner's design. The electrical circuits employed in intercommunication, switchboards, and signalling apparatus, as devised by him, have been adopted not only throughout this country, but in nearly all countries in the world.

Charles A. Coffin, founder and for thirty years head of the General Electric Company as president and chairman of the board of directors, died Wednesday night, July 14, 1926, at his home in Locust Valley, Long Island. He had been an Associate of the Institute since 1887.

Mr. Coffin was born in December, 1844, in Somerset County, Maine, and graduated from Bloomfield (Me.) Academy. His first business was in the shoe and leather industry, but in 1883 he became associated with the Thomson-Houston Electric Company in Lynn, Mass. In 1892 the Thomson-Houston Electric Company and the Edison General Electric Company of New York were consolidated and Mr. Coffin became president of the new General Electric Company. He has been called "the greatest organizing genius of the electrical industry in America" and was recognized as one of the greatest single factors making for the growth and development of the use of electricity in this country.

During the war Mr. Coffin was active in relief and Red Cross work and received the French Legion of Honor and the Belgian order of Leopold II. Yale, Union, and Bowdoin Colleges conferred honorary degrees upon him.

William H. Browne, 3rd, who was elected to the grade of Associate at the April 1926 meeting of the Institute Board of Directors, was killed in a railway accident on the 28th of June. Mr. Browne was the son of one of our Associates, William H. Browne, 2nd, of Raleigh N. C.; he was but twenty-six years of age and an operator for the McCollom Geological Exploration Corp.

Oberlin Smith, a Member of the Institute since 1913, died at his home in Bridgeton, N. J., on the 18th of July. At the time of his death he had been President and principal owner of the Ferracute Machine Company for more than sixty years.

Mr. Smith was born in Cincinnati on March 22, 1840, and was educated at the West Jersey Academy, Bridgeton, N. J., and at the Polytechnic Institute, Philadelphia. At the age of sixteen he became an apprentice at the Cumberland Nail and Iron Works; he next started a small machine shop and from that developed the Ferracute Machine Company.

He invented and patented fifty-two presses and dies, many of them used by the Government and in the Ford automobile plants. He also made the dies from which Chinese money is stamped.

Mr. Smith was formerly President of the American Society of Mechanical Engineers and the National Geographic Society. He was a member of the American Society of Civil Engineers, the Engineers Club of New York, and the Franklin Institute of Philadelphia.

Willis E. Osborne, for several years a resident engineer in the Orient for the Western Electric Company of London, and an Associate of the Institute, died at his home in Corsicana, Texas, on the 4th of July. Mr. Osborne was born in Pennsylvania in 1880 and received his education in that state.

Frank E. Goodnow, an Associate of the Institute since 1917, died in Evanston, Ill., on the 27th of May, after a long illness. He had been connected with the Public Service Company of Northern Illinois since 1909. Mr. Goodnow was a graduate of the Massachusetts Institute of Technology of the class of 1908.

William Yale Avery, electrical engineer for Gibbs Bros., Inc., New York City, and for the past six years a Member of the Institute, died suddenly July 5, 1926. Mr. Avery was born March 30, 1873 and at an early age started his electrical career, studying in the public schools at Providence, R. I., engineering night school, Tufts College and taking a special two years' course at Pratt Institute, Brooklyn in further night school work.

He later returned to Tufts College for another special electrical course. His professional experience embraced a varied and valuable training for later undertakings; draftsman for Brown & Sharp, Corliss Co., the Brooklyn Navy Yards on electrical ship equipment and installation, civilian in charge of electrical division of the Bureau of Equipment, Navy Dept., Washington, D. C., followed by work with the Bureau of Steam Engineering, in connection with ship electrical installations specifications for parts, purchase, etc. From 1919 to 1920 he was electrical engineer for the Electro Dynamic Co., Bayonne, N. J., handling navy, merchant marine and special motors and generators, inclusive of submarine equipment, etc. At one time Mr. Avery was affiliated also with the Cramp Shipbuilding Co. and Harlan & Hollingsworth.

Engineering Societies Library

The library is a cooperative activity of the American Institute of Electrical Engineers, the American Society of Civil Engineers, the American Institute of Mining and Metallurgical Engineers and the American Society of Mechanical Engineers. It is administered for these Founder Societies by the United Engineering Society, as a public reference library of engineering and the allied sciences. It contains 150,000 volumes and pamphlets and receives currently most of the important periodicals in its field. It is housed in the Engineering Societies Building, 29 West Thirty-ninth St., New York.

In order to place the resources of the Library at the disposal of those unable to visit it in person, the Library is prepared to furnish lists of references to engineering subjects, copies or translations of articles, and similar assistance. Charges sufficient to cover the cost of this work are made.

The Library maintains a collection of modern technical books which may be rented by members residing in North America. A rental of five cents a day, plus transportation, is charged.

The Director of the Library will gladly give information concerning charges for the various kinds of service to those interested. In asking for information, letters should be made as definite as possible, so that the investigator may understand clearly what is desired.

The library is open from 9 a. m. to 10 p. m. on all week days except holidays throughout the year except during July and August when the hours are 9 a. m. to 5 p. m.

BOOK NOTICES JUNE 1-30, 1926

Unless otherwise specified, books in this list have been presented by the publishers. The Society does not assume responsibility for any statement made; these are taken from the preface or the text of the book.

All books listed may be consulted in the Engineering Societies Library.

ARCHITECTURAL CONSTRUCTION, v. 2; An Analysis of the Structural Design of American Buildings. Book one: Wood Construction.

By Walter C. Voss and Edward A. Varney. N. Y., John Wiley & Sons, 1926. 224 pp., illus., diagrs., tables, 12 x 6 in., cloth. $6.50.

The aim of the authors is to present the modern practise of structural engineering as applied to architectural construction from the viewpoint of both the engineer and the architect. The present book, the first of several analyzing the structural design of buildings, is devoted to wood construction and deals primarily with mill buildings and the so-called second-class and third-class construction, in which more or less inflammable materials are used structurally.

The chapters discuss the design of beams, of floor construction, of roof construction, of columns and of miscellaneous framing. Each principle of design is analyzed, its relation to the entire building and to those architectural and structural details that control it is studied, and its application shown by illustrative problems.

BEGINNINGS OF THE NEW YORK CENTRAL RAILROAD.

By Frank Walker Stevens. N. Y., G. P. Putnam's Sons, 1926. 408 pp., illus., ports., map, 9 x 6 in., cloth. $4.00. (Gift of the New York Central Railroad Company).

A record of the early problems, trials, successes, failures and growth of the early railroads which were consolidated in 1853 to form the New York Central Railroad. The organization and history of the ten corporations which were consolidated is given, as it has been recovered from their surviving records, contemporary publications and letters, and much of interest is given about early matters of transportation, legislative regulation, and equipment. The book appears in the centennial year of the Mohawk and Hudson, the first of these roads.

CLAY PRODUCTS CYCLOPEDIA AND EQUIPMENT CATALOG. 3rd edition. 1926. Chicago, Industrial Publications, Inc., 1926. 336 pp., illus., 12 x 9 in., cloth. $3.00.

A combination of reference book and catalog of equipment for those engaged in making clay products. The text treats of many phases of manufacture, such as plant construction, power, fuels, conveyors, raw materials, drying, kilns, preparation of clays, molding and glazing. Condensed catalogs of a number of equipment makers are given. The book also contains a list of trade names, statistics, and a list of trade associations.

DIVERGENTE UND KONVERGENTE TURBULENTE STROMUNGEN MIT KLEINEN OFFNUNGSWINKELN.

By Fritz Donch. Ber., V. D. I. Verlag, 1926. (Forschungsarbeiten auf dem gebiete des Ingenieurwesens. Heft 282). 58 pp., diagrs., tables, 10 x 7 in., paper. 7,50 r. m.

This brochure presents the results of another of the series of investigations of fundamental problems in the flow of fluids which are being carried on at the Institute of Applied Mechanics in Gottingen, under Professor Prandtl's direction. Using air and a rectangular pipe with movable walls, the investigator examined the details of turbulent flow, especially convergent and divergent flow, from a unified point of view. Formulas are derived and the experimental results are evaluated.

DIE EDELSTAHLE, Ihre Metallurgische Grundlagen.

By F. Rapatz. Berlin, Julius Springer, 1925. 219 pp., illus., diagrs., tables, 8 x 5 in., boards. 12,-r. m.

This book aims to be an introduction to the study of alloy steels. The author has especially intended to show what properties are necessary for various purposes and what properties the steels now in use have.

After a brief introduction, the author discusses the uses of alloy steels and the demands made of them, the qualities that make for easy working, structure and heat treatment. The various steels are described and the method of manufacture explained. Methods of testing and imperfections are discussed.

ELEKTRISCHE SCHWINGUNGEN, vol. 1.

By Hermann Rohmann. Ber. u. Lpz., Walter de Gruyter & Co., 1926. 132 pp., 6 x 4 in., cloth. 1,50 r. m.

A revised edition of the first volume of a concise text on electric waves. After a brief summary of those matters of general electrical theory which are important in connection with them, the author discusses waves in condenser circuits, the generation of waves and the methods of measuring and investigating them. By using a terse style and confining himself to the bare essentials, the author has attained a very brief text.

ELEMENTARY TREATISE ON STATICALLY INDETERMINATE STRESSES.

By John Ira Parcel and George Alfred Maney. N. Y., John Wiley & Sons, 1926. 368 pp., diagrs., tables, 9 x 6 in., cloth. $5.00.

Aims to present the fundamental methods of attack on the problem of indeterminate stresses as clearly as possible and as fully as is consistent with an elementary treatise, and to illustrate the methods by applying them to some common types of indeterminate structures.

The first three chapters, comprising more than one-third of the book, give an exposition of the theory of elastic deflections and a

broad treatment of the general problem of indeterminate stresses. Chapters four to seven treat specifically the continuous girder, the rigid frame, the elastic arch, and secondary stresses. The final chapter contains a general discussion of statically indeterminate construction, a historical review and a good annotated bibliography.

FEUERVERSICHERUNG UND BRANDSCHADENABSCHATZUNG BEI MASCHINELLEN FABRIKEINRICHTUNGEN.

By Felix Moral. Berlin, V. D. I. Verlag, 1926. 102 pp., 8 x 6 in., paper. 2,80 r. m. (3,80 r. m. bound.)

A concise practical handbook on factory insurance. The author discusses under-insurance and over-insurance, the various kinds of insurance of plant equipment, special clauses for equipment insurance, the appraisal of machinery for insurance and the form of the policy. He also treats of expert appraisal of fire losses and of the determination of damages to machinery by fires.

HIGHWAY CURVES AND EARTHWORK.

By Thomas F. Hickerson. N. Y., McGraw-Hill Book Co., 1926. 382 pp., tables, 7 x 4 in., fabrikoid. $3.50.

A handbook on highway location which lays emphasis on the subject of curves and earthwork, including banking and widening of pavements. Includes a variety of original tables intended to facilitate the laying-out of easement spirals. A useful book for the engineer engaged in the design of modern highways for automobile traffic.

LANDESELEKTRIZITATSWERKE.

By A. Schonberg und E. Glunk, Mün. u. Ber., R. Oldenbourg, 1926. 398 pp., illus., diagrs., maps, 11 x 8 in., paper. 26.-mk.

A thorough, important discussion of the problem of centralized production and distribution of electricity, or, in other words, of superpower systems. The authors pay but little attention to such matters as hydraulic machinery, generating equipment, etc., but discuss thoroughly and in detail the broad technical, economic and legal questions involved in unified systems of generation and distribution. The object throughout is to call attention to correct methods for the economic utilization of natural power resources in the most efficient way.

The principles enunciated are illustrated by descriptions of various large German undertakings carried out by the firm of Oskar von Miller, of which the authors are technical managers.

LEHRGANG DER SCHALTUNGSSCHEMATA ELEKTRISCHER STARKSTROM-ANLAGEN, vol. 2; Schlatungsschemata für Wechselstrom-Anlagen.

By J. Teichmüller. Mün. u. Ber., R. Oldenbourg, 1926. 171 pp., plates in pocket, 13 x 9 in., cloth. 22,-mk.

A systematic presentation of alternating circuits, intended for use by students and engineers. Covers the excitation of alternators, synchronization, transformer circuits, voltage regulation, balancing, converter circuits, meter circuits in single-phase and triphase plants, control devices and over-loads. The second section of the book gives descriptions and diagrams of the wiring of nineteen actual plants selected to illustrate good current practise. The diagrams in the book are unusually satisfactory.

METAL-PLATE WORK; Its Patterns and Their Geometry.

By C. T. Millis. 5th edition. Lond., E. & F. N. Spon; N. Y., Spon & Chamberlain, 1926. 503 pp., diagrs., 8 x 5 in., cloth. 7/6.

Sets forth a system of geometric construction of the patterns for sheet-metal work which has been in use for over forty years. By it, nearly all the patterns required may be laid out on one geometric principle.

The new edition has been rearranged and enlarged.

MOVABLE BRIDGES, vol. 1; Superstructure.

By Otis Ellis Hovey. N. Y., John Wiley & Sons, 1926. 352 pp., illus., diagrs., tables, 9 x 6 in., cloth. $6.00.

The first volume of a treatise on the design of movable bridges and their machinery. This volume, on the superstructure, opens with a brief history of early designs. The author then discusses various types of movable bridges, giving statistical information intended to assist in determining the best type for particular conditions. The simplest and most practical methods of stress analysis are then discussed briefly, followed by a chapter on elastic deflections. Details of design are then discussed and there are chapters on rail joints, counterweights and houses for operators. Appendixes give an analysis of stresses in lenticular discs and a new method for designing tread plates for the supporting and segmental girders of rolling-lift bridges.

PHYSICAL CHEMISTRY FOR COLLEGES.

By E. B. Millard. 2nd edition. N. Y., McGraw-Hill Book Co., 1926. (International chemical series). 458 pp., diagrs., tables, 8 x 6 in., cloth. $3.50.

Aims to bring before the student certain of the more important aspects of physical chemistry, together with accurate data that illustrate the applicability of its laws to the phenomena observed in the laboratory. The new edition has been revised and some portions have been enlarged and rewritten.

PRACTICAL PAPER-MAKING.

By George Clapperton. 3rd edition, revised by R. H. Clapperton. Lond., Crosby & Son; N. Y., D. Van Nostrand Co., 1926. 220 pp., illus., 7 x 5 in., cloth. $2.50.

A concise manual for paper-makers, in which much practical advice is given on present day methods. The new edition follows closely the plan of previous ones, but has been changed by omitting obsolete methods and adding new ones, and by the addition of descriptions of new machinery.

DIE SCHALLTECHNIK.

By Richard Berger. Braunschweig, Friedr. Vieweg & Sohn, 1926. 115 pp., diagrs., 9 x 6 in., paper. 8,-r. m.

A summary of the present state of knowledge of acoustics. The monograph is intended to enable those not deeply informed to orient themselves quickly in this field, and also to point the directions in which research is needed.

STORY OF THE WESTERN RAILROADS.

By Robert Edgar Riegel. N. Y., Macmillan Co., 1926. 345 pp., 8 x 5 in., cloth. $2.50.

While there are many books on various phases of the railroad problem and on particular roads and railroad men, there has been practically no attempt, the author of this work says, to combine these into a general history of the railroads. The present book is an attempt to do this for the western roads.

The treatment is econonic and social and covers the period from 1852 to the early years of the present century when, in the view of the author, the western railroad net was completed. A considerable bibliography is included.

SUPERVISION OF VOCATIONAL EDUCATION OF LESS THAN COLLEGE GRADE.

By J. C. Wright and Charles R. Allen. N. Y., John Wiley & Sons, 1926. 415 pp., 8 x 6 in., cloth. $3.00.

This book, by the Director and the Editor of the Federal Board for Vocational Education, aims to place at the disposal of prospective and novice supervisors such portions of their own experiences as will assist them to improve their work. The topics discussed include the work of administrators and supervisors, qualifications, preparation, and methods of supervision.

UEBER DEN MARTENSIT.

By H. Hanemann and A. Schrader. Düsseldorf, Verlag Stahleisen, 1926. (Mitteilung aus der Metallographischen Abteilung des Eisenhüttenmannischen Laboratoriums der Technischen Hochschule zu Berlin). 25 pp., plates, 11 x 8 in., paper. 6,60 mk.

This brochure presents the results of an investigation of martensite undertaken to determine the soundness of a new hypothesis concerning its structure. Martensite, according to this hypothesis, contains two hitherto unknown phases of the iron-carbon alloys, different from alpha and beta iron. The methods of investigation and the results are given, with a discussion by various experts.

UNTERSUCHUNG UBER DIE GESCHWINDIGKEITSVERTEILUNG IN TURBULENTEN STROMUNGEN.

By J. Nikuradse. Berlin, V. D. I. Verlag, 1926. (Forschungsarbeiten auf dem Gebiete des Ingenieurwesens, Heft 281). 44 pp., illus., diagrs., tables, 11 x 8 in., paper. 6,-r. m.

Although the distribution of the velocities in turbulent flow is of great importance for its understanding and also for its

theoretical investigation, the present research is, the author says, the first undertaken on this point. This work gives the results of experiments on the distribution of velocities in closed channels and also on the surface of open channels.

Part one describes experiments on turbulent flow in pipes with circular, triangular and rectangular sections, giving the apparatus used, the method, and the results. Prandtl's law is derived from the consideration of dimensions, and the degree to which it corresponds with experimental results is shown.

In part two, the distribution of velocities in an open rectangular channel and on its surface is investigated. A comparison of distribution in open and in closed channels ends the work.

Workshop Operations and Lay-outs for Economic Engineering Production.

By Philip Gates. Lond., E. & F. N. Spon; N. Y., Spon & Chamberlain, 1926. 200 pp., illus., diagrs., 8 x 5 in., cloth. 7s 6d.

Aims to assist students and workmen to an understanding of methods for laying out machine-tool operations so as to ensure profitable production. The book deals with both small and heavy work and is illustrated by examples from English or American practise. Practically all the ordinary machine-shop operations are introduced.

Past Section and Branch Meetings

SECTION MEETINGS

Akron

Tire Testing by Means of the Sprague Dynamometer, by F. L. Haushalter, B. F. Goodrich Co. The following motion pictures were shown: "The Wizardy of Wireless;" "The King of the Rail" and "The Queen of the Waves." April 23. Attendance 30.

Radio Waves, by Dr. J. H. Dellinger, Bureau of Standards. The following officers were elected: Chairman, A. R. Holden; Secretary-Treasurer, H. L. Steinbach. May 7. Attendance 300.

Cincinnati

Annual Dinner. The following officers were elected: Chairman, W. P. Beattie; Secretary-Treasurer, L. J. Gregory. June 11. Attendance 36.

Cleveland

Mental Attitude, by Dr. M. I. Pupin, National President, A. I. E. E. A dinner preceded the meeting. The following officers were elected: Chairman, H. L. Grant; Secretary-Treasurer, W. E. McFarland. May 18. Attendance 102.

Detroit-Ann Arbor

Standard Distribution Systems, by B. L. Huff, Consumers Power Co., and

A-C. Low-Voltage Networks, by H. P. Seelye, The Detroit Edison Co. May 25. Attendance 125.

Traffic Control, by W. L. Potts, Detroit Police Department. Illustrated with slides. The following officers were elected: Chairman, Harold Cole; Vice-Chairman, A. H. Lovell; Secretary-Treasurer, F. H. Riddle. June 29. Attendance 60.

Fort Wayne

Annual Banquet. The following officers were elected: Chairman, D. W. Merchant; Vice-Chairman, P. O. Noble; Secretary-Treasurer, C. F. Beyer; Vice-Secretary-Treasurer, R. E. Pumphrey. June 3. Attendance 58.

Ithaca

In the Lands of Buddha, by Professor H. B. Smith, Worcester Polytechnic Institute. The following officers were elected: Chairman, R. F. Chamberlain; Secretary-Treasurer, G. F. Bason. May 14. Attendance 50.

Annual Banquet. Address by Dr. M. I. Pupin, National President, A. I. E. E. May 15. Attendance 180.

Lehigh Valley

Japanese Power Systems, by S. Q. Hayes, Westinghouse Electric and Mfg. Co. Illustrated by moving pictures.

"*Super Superior" Remote-Control Systems*, (humorous) by C. F. Crowder, H. N. Crowder, Jr., Company. Illustrated. A dinner preceded the meeting. May 21. Attendance 125.

Mexico

Business Meeting. June 10. Attendance 21.

Milwaukee

Automatic Substations, by Wm. E. Gundlach, The Milwaukee Elec. Ry. & Lt. Co. A motion picture, entitled "The Story of Anaconda," was shown. The following officers were elected: Chairman, H. L. Van Valkenberg; Secretary-Treasurer, P. B. Harwood. June 29. Attendance 55.

Minnesota

Present-Day Conditions in Mexico, by D. K. Lewis, Twin City Rapid Transit Co. The following officers were elected: Chairman, S. B. Hood; Secretary, M. E. Todd. June 16. Attendance 62.

Schenectady

Analysis of Railway Operations, by E. E. Kimball, General Electric Co. Illustrated with slides and moving picture. May 14. Attendance 300.

Social Meeting. May 22. Attendance 100.

Southern Virginia

Industrial Power Plants, by J. L. Jordan, Viscose Corp.;

Economy in Bridge Design, by P. A. Blackwell, Virginia Bridge and Iron Co.;

From Trees to Rayon, by Roy Smith, Viscose Corp., and

Wood Preservation, by J. H. Gibbony, N. & W. Railroad. Joint meeting with A. S. C. E. and A. S. M. E. May 21. Attendance 51.

Spokane

Business Meeting. The following officers were elected: Chairman, Richard McKay; Vice-Chairman, L. R. Gamble; Secretary-Treasurer, J. B. Fisken. May 21. Attendance 21.

Syracuse

Business Meeting. The following officers were elected: Chairman, C. E. Dorr; Secretary, F. E. Verdin. June 14. Attendance 10.

Business Methods Applied to City Government, by Mayor C. G. Hanna, and

Echoes of Life, by Dr. J. L. Davis. Annual Dinner of Technology Club and Affiliated Societies. June 14. Attendance 320.

Worcester

Operation of the New England Power System, by W. S. Cavanaugh, New England Power Co. The following officers were elected: Chairman, C. F. Hood; Vice-Chairman, G. F. Woodward; Secretary-Treasurer, F. B. Crosby. June 15. Attendance 45.

BRANCH MEETINGS

Rhode Island State College

Illumination of New York Central Railroad, by Mr. Hill. May 10. Attendance 14.

Carbon Dioxide as A Fire Extinguisher, by Mr. Barash;

Construction of Electric Welding Machines, by Mr. Penon, and

Applications of the Electric Welding Machine, by Mr. Easterbrooks. May 24. Attendance 12.

Business Meeting. The following officers were elected: Chairman, G. A. Eddy; Secretary, C. Easterbrooks. June 7. Attendance 16.

Engineering Societies Employment Service

Under joint management of the national societies of Civil, Mining, Mechanical and Electrical Engineers cooperating with the Western Society of Engineers. The service is available only to their membership, and is maintained as a cooperative bureau by contributions from the societies and their individual members who are directly benefited.

Offices:—33 West 39th St., New York, N. Y.,—W. V. Brown, Manager.
53 West Jackson Blv'de., Room 1736, Chicago, Ill., A. K. Krauser, Manager.
57 Post St., San Francisco, Calif., N. D. Cook, Manager.

MEN AVAILABLE.—Brief announcements will be published without charge but will not be repeated except upon requests received after an interval of one month. Names and records will remain in the active files of the bureau for a period of three months and are renewable upon request. Notices for this Department should be addressed to **EMPLOYMENT SERVICE, 33 West 39th Street, New York City,** *and should be received prior to the 15th of the month.*

OPPORTUNITIES.—A Bulletin of engineering positions available is published weekly and is available to members of the Societies concerned at a subscription rate of $3 per quarter, or $10 per annum, payable in advance. Positions not filled promptly as a result of publication in the Bulletin may be announced herein, as formerly.

VOLUNTARY CONTRIBUTIONS.—Members obtaining positions through the medium of this service are invited to cooperate with the Societies in the financing of the work by nominal contributions made within thirty days after placement, on the basis of $10 for all positions paying a salary of $2000 or less per annum; $10 plus one per cent of all amounts in excess of $2000 per annum; temporary positions (of one month or less) three per cent of total salary received. The income contributed by the members, together with the finances appropriated by the four societies named above, will it is hoped, be sufficient not only to maintain, but to increase and extend the service.

REPLIES TO ANNOUNCEMENTS.—Replies to announcements published herein or in the Bulletin, should be addressed to the key number indicated in each case, with a two cent stamp attached for reforwarding, and forwarded to the Employment Service as above. Replies received by the bureau after the positions to which they refer have been filled will not be forwarded.

POSITIONS OPEN

ELECTRICAL ENGINEER, with electrical engineering degree and at least three years' design, test or laboratory experience. Heating experience an advantage. Salary, $45-$65 a week. Apply by letter. Location, Middlewest. X-219C.

GRADUATE ELECTRICAL ENGINEER, experienced in small electric motors, to establish sales department with company manufacturing electric appliances. Opportunity. Apply by letter, with full details of age, past employment and salary, and lowest salary to start. Location, Middlewest. X-117.

ENGINEER, experienced, to handle disconnecting switch business for electrical apparatus manufacturer. Man with designing and field erection experience desired. Must be able to conduct correspondence. Opportunity. Apply by letter. Location, Pennsylvania. X-156C.

MEN AVAILABLE

ELECTRICAL GRADUATE, age 24, single, desires permanent position engineering work. One year test, one year carrier-current field engineering with General Electric Company. Familiar with utilities of the South. C-1391.

EXECUTIVE ENGINEER, electric engineer, or maintenance engineer, electrical engineer with fourteen years' central station and engineering experience supplemented by consulting, construction and State public service commission engineering work. Can win and hold the public's confidence and handle others efficiently and quietly. Age 42. United States preferred. C-1509.

ELECTRICAL ENGINEER, 28, married, three years' experience in testing, research and development work on electrical appliances, four years' experience in engineering department of large public utility, desires position in large manufacturing company in connection with design of electrical apparatus and its application to central station systems. Salary $250 a month minimum. Location, Ohio, Pennsylvania, or New York preferred. B-4362.

INSTRUCTOR OF MATHEMATICS—MECHANICAL DRAWING, 24, single. Has tutored in mathematics for three years. Has taught in Friends' School as physical training instructor. Available July 15th. Location, New York City. C-1514.

GRADUATE INDUSTRIAL ELECTRICAL ENGINEER, 27, married, desires position with engineering, manufacturing or construction firm. Seven years' experience in industrial plant engineering. Excellent references from former employers and plants in which I have installed electrical equipment. Location, vicinity of New York. C-1636.

ELECTRICAL ENGINEER, engineering and arts graduate with production, scheduling, budgeting, valuation, some design, operating and construction experience. Available as assistant executive or department head of operating holding or manufacturing company. Nine years' experience, five years utilities and four years industries. Married, age 30. Now with large utility. Available in two months. B-9676.

ELECTRICAL ENGINEER, desires position as operating or distribution engineer. Age 27; married, technical education. Two years G. E. test, three years electrical superintendent of large industrial plant, and two years with utility company serving 12,000 customers as distribution engineer. Salary $225. Available two weeks' notice. B-9390.

SALES ENGINEER, 29, married, desires to represent manufacturer in Chicago and Middlewestern territory. University electrical engineering graduate. Six years' experience selling to dealers, jobbers and manufacturers. C-1651.

ASSISTANT EXECUTIVE B. S. and E. E. degrees, five years' well balanced experience in all phases of distribution and power substations and their commercial aspects, and one year's experience in administrative office of manufacturing company. Three years in supervisory capacity. Desires position with electrical company requiring technical, commercial and executive ability. Minimum salary $3600. Location preferred, lower Great Lakes States. B-7315.

MANAGER, 37, married, redesign machinery and processes, origination new products, installation new departments, purchase new businesses, installation shop control. Sixteen years' experience large and moderate sized manufacturing plants. Graduate engineer. Employed at present as departmental manager. Available on one month's notice. Location, Wisconsin. C-1050.

HYDROELECTRIC DRAFTING, 28, single, graduate electrical engineer class 1924, desires to make a start with hydro-electric engineering firm as draftsman. Can produce specimens of work. Available in ten days. Location preferred Chicago. B-8850.

PROFESSORSHIP in electrical engineering wanted by graduate of Harvard University with thirteen years' university teaching experience, and five years (in addition to numerous summers) in varied practise. Specialist in high voltage transmission research, theory, design and practise. Important experience with both Westinghouse and G. E. Companies. Age 43, married, excellent health, best of references. C-577-2-C-15.

ELECTRICAL ENGINEER AND PHYSICIST, 34, graduate several schools, on instruction staff well known institution for five years. Extensive development experience on apparatus, also patent experience. Position in the development of electrical instruments desired. Thorough practical and theoretical knowledge of electricity. Location preferred, Philadelphia. B-165.

ASSISTANT EXECUTIVE, well balanced experience of thirteen years on cost analysis industrial processing, commercial statistics, advertising, administrative control. Seven years with large company servicing subsidiaries and clients. Public utility experience. Technical graduate, married, age 34. Prefers administrative or commercial to strictly technical. Location, New York, New England. Available reasonable notice. B-9122.

RECENT UNIVERSITY GRADUATE of Marquette University, College of Engineering, holding a Professional Degree in Electrical Engineering, havingt two years of practical experience in large steel foundry and manufacturing plant; also several months of heat-treating and specialty work. After one week's notice, anywhere in the U. S. C-1438.

MANUFACTURER'S AGENT, electrical engineer having ten years' engineering and selling experience in New England desires to represent manufacturer of electrical or allied lines in this territory on minimum salary and commission basis. Now located with internationally known electrical manufacturer. Available two weeks' notice. A-1330.

ELECTRICAL GRADUATE, American born and educated, English descent, desires foreign service with some reputable company. Good personality, good appearance, engineering experience, ambitious, and a willing worker, employed at present. Only foreign service desired, preferably

in Germany, France, Sweden, or some British Possession. C-1658.

TECHNICAL GRADUATE, B. S., (E. E.). Westinghouse Factory training, one year on road as Service Engineer. Three years as Chief Electrician for Reclamation Service, Wyoming Project, completely in charge of Hydro-Installation and Power Lines, Electrification of draglines, shops, etc. Age 28. Mechanic and not office man. Can do all repair work in shop winding bearings, switchboards, etc. Handle men well and have trained crew. Salary not less than $250. Will appreciate correspondnece. C-1680.

INDUSTRIAL ELECTRICAL ENGINEER, technical graduate, 27, completed Westinghouse Engineering graduate student course. Experience in testing and in the industrial engineering department of the Westinghouse Company plus actual experience in the industry. Desires position as industrial sales or efficiency and testing engineer. Possibilities for advancement and where initiative and ability are recognized. Excellent references can be furnished. Available on reasonable notice. B-8918.

MEMBERSHIP — Applications, Elections, Transfers, Etc.

APPLICATIONS FOR ELECTION

Applications have been received by the Secretary from the following candidates for election to membership in the Institute. Unless otherwise indicated, the applicant has applied for admission as an Associate. If the applicant has applied for direct admission to a higher grade than Associate, the grade follows immediately after the name. Any member objecting to the election of any of these candidates should so inform the Secretary before August 31, 1926.

Berthold, W., New York Rapid Transit Corp., Brooklyn, N. Y.
Bricker, G. W., Jr., with H. C. Hopson, Inc., New York, N. Y.
Broome, G. W., Stevens & Wood, Inc., New York, N. Y.
(Applicant for re-election.)
Brummal, J. S., Kansas City Telephone Co., Kansas City, Mo.

RECOMMENDED FOR TRANSFER

The Board of Examiners, at its meetings held May 17, June 11, and July 26, 1926, recommended the following members for transfer to the grade of membership indicated. Any objection to these transfers should be filed at once with the National Secretary.

To Grade of Fellow

BOLSER, M. O., Assistant Electrical Engineer, Department of Water and Power, City of Los Angeles, Calif.
CRAFT, EDWARD B., Executive Vice President, Bell Telephone Laboratories, New York, N. Y.
KELLY, WILL G., Assistant Engineer of Distribution, Commonwealth Edison Co., Chicago, Ill.
MacCUTCHEON, A. M., Engineering Vice President, Reliance Electric and Engineering Co., Cleveland, Ohio.
POWELL, ALVIN L., Manager, Engineering Dept., Edison Lamp Works, Harrison, N. J.
SILVER, ARTHUR E., Consulting Electrical Engineer, Electric Bond & Share Co., New York, N. Y.

To Grade of Member

AMBROSE, FREDERIC B., Engineer, Duquesne Light Co., Pittsburgh, Pa.
BENHAM, C. F., Asst. to General Supt., Great Western Power Co., San Francisco, Calif.
BLACKWELL, EDWARD S., Asst. Supt. of Construction, Div. of Construction & Engineering, Stone & Webster, Inc., Pinehurst, Wash.

WAITE, LESLIE O., Engineer, Stone & Webster, Inc., Boston, Mass.
WALLIS, CHARLES R., Sales Engineer, General Electric Co., Seattle, Wash.
WALTHER, JOHN T., Professor of Electrical Engineering, Municipal University of Akron, Akron, Ohio.
WARD, RALPH B., Chief, Electrical Bureau, Newark, N. J.
WATKINS, SAMUEL S., Electrical Engineer, Gibbs & Hill, New York, N. Y.
WIESEMAN, Special Designing Engineer, A. C. Engg. Dept., General Electric Co., Schenectady, N. Y.
WILSON, HARRY R., Central Station Engineering Dept., General Electric Co., Schenectady, N. Y.
WOOD, EDWIN D., Electrical Operating Engineer, Louisville Gas & Electric Co., Louisville, Ky.
WOODS, GEORGE M., General Engineering, Westinghouse Electric & Mfg. Co., East Pittsburgh, Pa.
WOODSON, J. C., Manager, Industrial Heating Engineering Dept., Westinghouse Electric & Manufacturing Co., Mansfield, Ohio.
YERXA, RUSSELL A., Electrical Supt., Dwight P. Robinson & Co., New York, N. Y.

OFFICERS OF A. I. E. E. 1926-1927

President

C. C. Chesney

Junior Past Presidents

M. I. Pupin — Farley Osgood

Vice-Presidents

P. M. Downing — H. M. Hobart
Herbert S. Sands — B. G. Jamieson
W. E. Mitchell — George L. Knight
Arthur G. Pierce — H. H. Schoolfield
W. P. Dobson — A. E. Bettis

Managers

William M. McConahey — M. M. Fowler
W. K. Vanderpoel — H. A. Kidder
H. P. Charlesworth — E. C. Stone
John B. Whitehead — I. E. Moultrop
J. M. Bryant — H. C. Don Carlos
E. B. Merriam — F. J. Chesterman

National Treasurer — George A. Hamilton

National Secretary — F. L. Hutchinson

Honorary Secretary

Ralph W. Pope

LOCAL HONORARY SECRETARIES

T. J. Fleming, Calle B. Mitre 519, Buenos Aires, Argentina, S. A.
Carroll M. Mauseau, Caixa Postal No. 571, Rio de Janiero, Brazil, S. A.
Charles le Maistre, 28 Victoria St., London, S. W. 1, England.
A. S. Garfield, 45 Bd. Beausejour, Paris 16 E, France.
F. W. Willis, Tata Power Companies, Bombay House, Bombay, India.
Guido Semenza, 39 Via Monte Napoleone, Milan, Italy.
P. H. Powell, Canterbury College, Christchurch, New Zealand.
Axel F. Enstrom, 24a Grefturegatan, Stockholm, Sweden.
W. Elsdon-Dew, P. O. Box 4563, Johannesburg, Transvaal, Africa.

A. I. E. E. COMMITTEES

The list of committees is omitted from this issue, as new appointments are being made for the administrative year beginning August 1. The new committees will be listed in the September issue.

A. I. E. E. REPRESENTATION

A complete list of A. I. E. E. representatives on various bodies will be published in the September issue.

LIST OF SECTIONS

Name	Chairman	Secretary
Akron	A. R. Holden	H. L. Steinbach, Electrical Engineering Dept., Goodyear Tire & Rubber Co., Akron, Ohio
Atlanta	W. E. Gathright	W. F. Oliver, Box 2211, Atlanta, Ga.
Baltimore	W.B. Kouwenhoven	R. T. Greer, Madison St. Building, Baltimore, Md.
Boston	J. W. Kidder	W. H. Colburn, 39 Boylston St., Boston, Mass.
Chicago	K. A. Auty	William Wurth, 1634 Peoples Gas Bldg., Michigan Ave. at Adams St., Chicago, Ill.
Cincinnati	W. P. Beattie	L. J. Gregory, Union Gas & Electric Co., Cincinnati, Ohio
Cleveland	H. L. Grant	W. E. McFarland, 720 Illuminating Bldg., Cleveland, Ohio
Columbus	R. J. B. Feather	W. T. Schumaker, 25½ North High St., Columbus, Ohio
Connecticut	A. E. Knowlton	R. G. Warner, Yale University, 10 Hillhouse Ave., New Haven, Conn.
Denver	W. H. Edmunds	R. B. Bonney, Telephone Bldg., P. O. Box 960, Denver, Colo.
Detroit-Ann Arbor	Harold Cole	F. H. Riddle, Champion Porcelain Co., Detroit, Mich.
Erie	F. A. Tennant	L. H. Curtis, General Electric Co., Erie, Pa.
Fort Wayne	D. W. Merchant	C. F. Beyer, General Electric Co., Fort Wayne, Ind.
Indianapolis-Lafayette	H. M. Anthony	J. D. Bailey, 48 Monument Circle, Indianapolis, Ind.
Ithaca	R. F. Chamberlain	G. F. Bason, Electrical Engineering Dept., Cornell University, Ithaca, N. Y.
Kansas City	R. L. Baldwin	S. M. De Camp, 510 Dwight Bldg., Kansas City, Mo.
Lehigh Valley	W. E. Lloyd, Jr.	G. W. Brooks, Pennsylvania Power & Light Co., 8th & Hamilton Sts., Allentown, Pa.
Los Angeles	R. E. Cunningham	L. C. Williams, H. W. Hellman Bldg., Los Angeles, Calif.
Lynn	E. D. Dickinson	F. S. Jones, General Electric Co., Lynn, Mass.
Madison	E. J. Kallevang	H. J. Hunt, D. W. Mead & C. V. Seastone, State Journal Bldg., Madison, Wis.
Mexico	E. F. Lopez	H. Larralde, Isabel La Catolica, 33 Mexico, D. F., Mexico
Milwaukee	H.L.VanValkenberg	P. B. Harwood, Cutler Hammer Mfg. Co., Milwaukee, Wis.
Minnesota	S. B. Hood	M. E. Todd, University of Minnesota, Minneapolis, Minn.
Nebraska	C. W. Minard	N. W. Kingsley, 1303 Telephone Bldg., Omaha, Nebr.
New York	E. B. Meyer	O. B. Blackwell, American Tel. & Tel. Co., 195 Broadway, New York, N. Y.
Niagara Frontier	H. B. Alverson	A. W. Underhill, Jr., 606 Lafayette Bldg., Buffalo, N. Y.
Oklahoma	E. R. Page	C. C. Stewart, Oklahoma Gas & Electric Co., Norman, Okla.
Panama	L. W. Parsons	I. F. McIlhenny, Box 413, Balboa Heights, C. Z.
Philadelphia	Nathan Shute	R. H. Silbert, 2301 Market St., Philadelphia, Pa.
Pittsburgh	W. C. Goodwin	D. M. Simons, Standard Underground Cable Co., Cor. 17th & Pike Sts., Pittsburgh, Pa.
Pittsfield	E. F. Gehrkens	C. H. Kline, General Electric Co., Pittsfield, Mass.
Portland, Ore.	J. C. Henkle	J. E. Yates, Gasco Bldg., Portland, Ore.
Providence	Edwin E. Nelson	F. W. Smith, Blackstone Valley Gas & Electric Co., Pawtucket, R. I.
Rochester	Earl C. Karker	J. Rowley Clark, 25 Favor St., Rochester, N. Y.
St. Louis	W. H. Millan	L. N. Van Hook, 3869 Park Ave., St. Louis, Mo.
San Francisco	R. C. Powell	A. G. Jones, 807 Rialto Bldg., San Francisco, Calif.
Saskatchewan	S. R. Parker	W. P. Brattle, Dept of Telephones, Telephone Bldg., Regina, Sask.
Schenectady	R. E. Doherty	R. F. Franklin, Room 301, Bldg. No. 41, General Electric Co., Schenectady, N. Y.
Seattle	C. E. Mong	C. R. Wallis, 609 Colman Bldg., P. O. Box 1858, Seattle, Wash.
Sharon	H. L. Cole	L. E. Hill, Westinghouse Elec. & Mfg. Co., Sharon, Pa.
Southern Virginia	W. S. Rodman	J. H. Berry, 1338 Rockbridge Ave., Norfolk, Va.
Spokane	Richard McKay	James B. Fisken, Washington Water Power Co., Lincoln & Trent, Spokane, Wash.
Springfield, Mass.	L. F. Curtis	J. Frank Murray, United Electric Light Co., 251 Wilbraham Ave., Springfield, Mass.
Syracuse	C. E. Dorr	F. E. Verdin, 615 City Bank Bldg., Syracuse, N. Y.
Toledo	A. H. Stebbins	Max Neuber, 1257 Fernwood Ave., Toledo, Ohio
Toronto	M. B. Hastings	F. F. Ambuhl, Toronto Hydro-Electric System, 226 Yonge St., Toronto, Ontario
Urbana	J. T. Tykociner	L. B. Archer, 308 Electrical Engineering Lab., University of Illinois, Urbana, Ill.
Utah	John Salberg	D. L. Brundige, Utah Power & Light Co., Box 1790, Salt Lake City, Utah
Vancouver	R. L. Hall	C. W. Colvin, B. C. Electric Railway Co., 425 Carrall St., Vancouver, B. C.

DIGEST OF CURRENT INDUSTRIAL NEWS

NEW CATALOGUES AND OTHER PUBLICATIONS

Mailed to interested readers by issuing companies

Control Apparatus.—Booklet, 36 pp., entitled "Industry's Electrical Progress." Describes numerous applications of C-H equipment for electrical control. The Cutler-Hammer Manufacturing Co., Milwaukee, Wis.

Motors.—Bulletin 106, 4 pp. Describes direct and alternating-current crane and hoist motors. Bulletin 102, 4 pp., describes direct-current motors ¼ to 150 h. p. Northwestern Manufacturing Company, Milwaukee, Wis.

Marine-Electric Oil Engines.—Booklet, 24 pp. entitled "Marine Oil Engines for Direct and Electric Drive." Attractively illustrated with typical installations. Ingersoll-Rand Company, 11 Broadway, New York.

Molybdenum Steel in Ball Bearings.—Booklet, 8 pp. entitled "Mo-lyb-den-um Means More-Life-in-'em" describes the development and use of molybdenum steel for bearing purposes. Standard Steel & Bearings, Inc., Plainville, Conn.

Relays.—Bulletin 550, 8 pp. Describes Roller-Smith new type SR line of relays. These supersede the old Imperial type of relays and have many marked advantages over the old type. The scales are longer, the accuracy is much greater and the torque has been increased several times. The new 7½ inch round pattern style of case matches type SA and type SD lines of indicating instruments. The Roller-Smith Company, 12 Park Place, New York.

Copperweld Wire.—Bulletin E. D. 502, 6 pp. The economic reasons justifying the use of copperweld guy, messenger and span wire are set forth by both text and tables in this publication. The claim is made that copperweld wire effects a saving of 90% over the final cost of materials that rust and have to be replaced. Included in the bulletin are sketches showing guying and messenger cable construction in standard use. Copperweld Stee Company, Rankin, Pa.

NOTES OF THE INDUSTRY

Large Orders to Westinghouse.—The Westinghouse Electric & Manufacturing Company has received an order for the largest horizontal waterwheel generators ever built, consisting of two 45,000 kv-a. units. These will form the No. 1 and No. 2 units of the Southern California Edison Company's Big Creek 2-A station. The generators will be totally enclosed, and complete with suitable direct connected exciters and usual accessories. Their total weight will be about 600,000 lbs. each, the overall width and height being approximately 25 feet and 23 feet respectively. The length of the generator itself will be about 14 feet.

Three of the main generators for the Conowingo development now being undertaken by the Philadelphia Electric Company will be furnished by the Westinghouse Company. They are of the vertical type, rated at 40,000 kv-a. each. In addition, the Westinghouse Company was awarded two 1600 kv-a. vertical water wheel generators and exciters, the total contract amounting to considerably above $1,000,000.

Among other orders recently received is one from the Union Electric Light and Power Company, McClellan & Junkersfeld, Inc., engineers, for the third section of the Cahokia plant. This order amounts to approximately $200,000 and calls for twenty-two, segregated phase, type 0-33, oil circuit breakers and three single pole grounding breakers, with associated control equipment, consisting of control desk, and relay and instrument boards. Eleven of these breakers will be of the type 0-33, 3000 ampere, three-pole, and eleven of the 600 ampere, three-pole, type 0-33. The remaining three will consist of type 0-33 neutral, 1200 ampere, single pole breakers.

New York Office for Cook Porcelain Insulator Corporation.—The Cook Porcelain Insulator Corporation, Cambridge, Ohio, manufacturers of high-tension insulators, announces the establishment of a New York office located at 161 Grand Street. Mr. J. H. Parker, formerly associated with the General Porcelain Company, has been appointed eastern sales representative, with headquarters in New York.

First Half of 1926 Brings Increased Business to G-E.—Orders received by the General Electric Company for the first six months of 1926 totaled $165,405,720, representing an increase of 10 per cent over the $150,315,228 booked in the corresponding six months of 1925, President Gerard Swope has announced. For the three months ending June 30 this year, orders totaled $78,972,062, compared with $66,468,992 for the second quarter of 1925, an increase of 19 per cent. In the first six months of this year there were 152 working days, including Saturdays, showing General Electric orders received thus far this year have been at a rate of better than $1,000,000 per day.

The company will hereafter report its earnings quarterly to the stockholders. The dividend date has been changed from the 15th to about the 25th of the month, and the next quarterly dividend will be payable on or about October 25, 1926, and will be accompanied by a statement of orders received and earnings for the first nine months of this year.

New Factory for Absolute Contactor Company. The Absolute Contactor Company has let the contract for the construction of its new factory building at Elkhart, Ind. Greatly increased plant facilities will enable the company to take care of its rapidly expanding business. The factory at Beloit, Wis., will continue in production pending the completion of the new plant.

H. D. Randall Now Sales Manager of G-E Gear Section.—H. D. Randall has been made sales manager of the gear section of the industrial department of the General Electric Company. He will have his headquarters at the River Works, West Lynn, Mass. The non-metallic gear business has developed rapidly during the last few years and it is expected that under Mr. Randall's direction it will continue to expand.

Kuhlman Electric Company, Bay City, Mich., manufacturers of power, distribution and street lighting transformers, announces the establishment of a factory office at 3-260 General Motors Building, Detroit. Richard P. Johnson will have charge of this office.

It is also announced that the Continental Sales & Engineering Company, 839 Oliver Bldg., Pittsburgh, Pa., have been appointed Kuhlman district representatives. Henry M. Hughes is manager of the company.

Largest Synchronous Condensers to be Built.—Synchronous condensers of far greater capacity than any ever previously built are being constructed by the General Electric Company for the Southern California Edison Company, for regulating the voltage along the transmission lines which carry power from remote hydroelectric developments into Los Angeles. Each of the three condensers is rated at 50,000 kv-a., 13,200 volts, 50 cycles, 600 revolutions per minute. Two are to be installed in the new Lighthipe substation and the other in the Eagle Rock substation. The largest synchronous condensers previously constructed by the General Electric Company have a capacity of 30,000 kilowatts each; condensers of this size are now being used in the Laguna Bell and Eagle Rock substations of the company. With the condenser the G-E Company is also supplying the necessary transformers. These nine units, three for each condenser, are of 16,700 kv-a. capacity each, and have forced coil air pressure cooling. They have 73,000-volt primary and 13,000-volt secondary windings.

Work of the A. I. E. E. Sections Committee

The Institute was founded in 1884. By 1900 it had attained a membership of 1142. In 1902-3, under the administration of President C. F. Scott, the establishment of Sections and Branches was approved and encouraged. Five years later, in 1907, there were 19 Sections and 17 Branches, with a total membership in the Institute of 4861. Together with the rapidly developing profession of electrical engineering and the impetus given by the activities of the Institute and its Sections and Branches, there has come the remarkable growth of the Institute during the last twenty years. This is indicated by the following tabulation:

Year	National Membership	No. of Sections	No. of Sections Meetings	Total Attendance at Sections Meetings	Amount of Sections Budget
1909	6,400	24	169	16,427	3,389.51
1913	7,654	29	244	22,825	12,645.18*
1917	8,710	32	265	31,299	10,596.96
1921	13,215	42	303	37,823	20,563.89
1924	15,438	47	381	58,945	25,219.31
1925	17,319	49	386	49,029	27,309.52
1926	18,158	51	405	58,959	30,060.76

The accelerated activities of the Sections and the Sections Committee were probably first clearly evident in connection with the work of the Sections Delegates Conference of 1921, conducted at Salt Lake City by the Sections Committee. Here it was evident that the Sections Delegates Conference was becoming an effective and important agency in the shaping of Institute policy through its recommendations to the Board of Directors. This is a natural result of the normal operation of such a body as defined by the Constitution and By-Laws and made up, as it is, of representatives from all the Sections distributed throughout the country.

That this is the case and the importance of the work done is shown by the following statement of some of the present policies now actively in force but which may be traced to initial action and recommendation of the Sections Committees and the Sections Delegates Conferences of the past few years.†

*Including an item of $4,345.29 for special and unusual expenditure.

†See printed report of Sections Delegates Conference, White Sulphur Springs, June 21, 1926.

1. *Delegates' Conferences*

1916 Program Committee to formulate program for annual conference and mail it to the Delegates in advance.

1922 Meetings to be held annually on the day before the Summer Convention proper begins.

2. *Local Affiliations*

1916 Subcommittee to report.

1918 Committee reported.

1919 Request for further study, resulting in the appointment of a special committee by the national societies.

1924 Statement of policy prepared and approved by the governing bodies of all four Founder Societies.

1925 Subject given further study and previous statement of policy approved.

1926 Recommendation to the Board of Directors for appointment of a special committee on contacts with the public for further study and report. Committee appointed.

3. *Geographical Districts*

1919 Division of the country into ten Districts and election of a Vice-President from each District.

1923 Traveling expenses to be authorized for the members of the Executive Committee of each District to one meeting each year.

4. *Vice-Presidents*

1923 Increase terms of Vice-Presidents from one to two years and provide that no Director shall hold office for more than six consecutive years.

1924 Traveling expenses authorized for one visit each year of each Vice-President to all Sections in his District.

5. *Publications*

1919 to 1923 Recommendations made which have resulted in the present well-defined policy regarding the Institute publications.

6. *Transfers*

1923 Plan recommended whereby desirable candidates for transfer to higher grades may be recommended to the Board of Examiners by other members.

7. *Prizes*

1923 First Paper and Best Paper Prizes for each District recommended. Now available.

1925 Recommended that a committee be appointed to prepare a statement of policy and procedure in connection with all national and regional prizes. Appointed and reported. 34 annual prizes now available.

8. *Finances*

1922 Recommended that the basis of financial support for Sections be changed from $100.00 flat plus $1.25 per member, to $175 flat per Section plus $1.00 per member. Now in force.

1922 Recommended that Sections be left free to expend their appropriations as they deemed best, but to send a report of expenditures to headquarters for the Finance Committee. Now in force.

9. *Branches and Counselors*

1925 Recommendation that a counselor be appointed for each Student Branch, these counselors in all cases to be members of the Institute and of the faculty in the institution in which their Branch is located.

1926 Recommended payment of travel expenses of counselors and Branch chairmen to Regional conventions and of District

Branch representatives to Sections Delegates Conferences. Approved by Directors. Referred to Finance Committee.

10. Speakers' Bureau

1922 Action taken to establish a speakers' bureau in limited form.

1926 Recommendation for appointment of a special committee to study question of public relations and development of more effective plan of speakers' bureau. Committee appointed.

11. Regional Meetings

1923 to 1926 Present policy of holding meetings under the auspices of the Geographical District officers developed. Regional meetings have been held as follows:

No. of Meeting	District	Location	Dates	Technical Papers	Attendance
1	No. 1	Worcester, Mass.	June 5, 6, 1924	9	275
2	No. 2	Washington, D. C.	Jan. 23, 24, 1925	6	212
3	No. 1	Swampscott, Mass.	May 7, 8, 1925	21	370
4	No. 2	Cleveland, Ohio	March 18, 19, 1926	3	430
5	No. 5	Madison, Wis.	May 6, 7, 1926	9	180
6	No. 1	Niagara Falls, N.Y.	May 26, 27, 28, 1926	23	330

Plans are already under way for similar regional meetings of Section and Branch membership for the coming Institute year for Districts No. 1, 2, 3; 5, 8, 9, and it is expected that this list may be extended in the course of the year.

The accomplishments of recent years point the way to further advisable activites for the Institute membership in its effective Section and committee work for the future. The relations of the Section membership to neighboring membership of other technical and professional societies, to the Institute Student Branch membership, to its District and National Membership, to the general public and to itself are interesting and profitable fields for study. It is hoped that tangible and important results will come in the near future from the study in committees now being given to these relationships.

HAROLD B. SMITH,
Chairman, Sections Committee.

Some Leaders of the A. I. E. E.

Comfort A. Adams, the 31st president of the Institute, 1918-1919, was born in Cleveland, Ohio, Nov. 1, 1868. His early education in the public schools of Cleveland was followed by four years at Case School of Applied Science from which he received the degree of B. S. in Electrical and Mechanical Engineering in 1890, the degree of E. E. in 1905 and in 1925 the honorary degree of Doctor of Engineering. During three years of his undergraduate period, Mr. Adams was assistant to Dr. A. A. Michelson in the Physical Laboratory.

After spending the summer of 1890 on a scientific expedition of explorations and surveys of the Muir Glacier district, Alaska, he served four months as engineer for the Brown Hoisting and Conveying Machine Co. of Cleveland and then joined the Engineering Staff of the Brush Electric Co. of Cleveland where under Sidney Short he took part in the design of the first geerless railway motor.

In September 1891, he accepted an appointment as Instructor in Electrical Engineering at Harvard University, was made Assistant Professor in 1895 and Professor of Electrical Engineering in 1905. Since 1914, he has been Lawrence Professor of Engineering.

When the Harvard Engineering School reorganized after the war, Prof. Adams was appointed Dean, but resigned shortly thereafter to accept the chairmanship of the Div. of Engineering National Research Council.

He has served in the capacity of consulting engineer for a large number of clients including Stone & Webster; American Tool and Machine Co.; The Okonite Co.; Edison Illuminating Company of Boston; Public Service Electric Company of N. J.; American Sugar Refining Co.; Warner Sugar Refining Co.; National Cable & Conduit Co., etc.

He has served the Institute as manager, vice-president and president; also as chairman of the Standards Committee; chairman of the Edison Medal Committee; chairman of the Committee on Code of Professional Conduct; and as member of several other committees, including the U. S. Committee of the International Electrotechnical Commission.

He has been very active also in the cooperation movement of the Engineering Societies, having organized the American Engineering Standards Comm. and being its first chairman. He reorganized the Engineering Division of the National Research Council after the war, serving as its chairman for two years. He was a member of the first American Engineering Council, took part in the organization of the Federated Am. Engineering Societies, has since continued on its Council and on the present Am. Engineering Council. He also served as member and president of the John Fritz Medal Board of Award.

He is author of several important papers in the general field of the theory and design of electrical machinery presented before the Institute during the past 20 years. His contributions to induction motor design were particularly significant.

During the world war he served as chairman of the General Engineering Committee of the Edison Commission of the Council of National Defense; chairman of the Welding Committee of the Emergency Fleet Corporation and chairman of the Electrical Engineering Section of the National Research Council.

Prof. Adams is a member of the A. S. C. E., A. S. M. E., S. A. E., A. S. T. M., N. E. L. A. and of the British Inst. of Elec. Engrs.; a fellow of the Am. Academy of Arts & Sciences, Am. Assoc. for the Advancement of Science and of the American Physical Society. He organized and was first president of the Am. Welding Society of which he is now an honorary member. He is also Director of the Am. Bureau of Welding.

Electrical Practise in the Lead-Silver Mines of Utah

BY LEONARD WILSON[1]

Non-member

Synopsis.—*Special features of industry react on selection of equipment. Speed of conducting operations directly affects value of property; the mining personnel has a somewhat unique psychology; the cost of providing space underground is enormous. Certain requirements result and equipment must be selected accordingly.*

Compressed air has been the only power medium and still reigns supreme for rock drills. Electric power has captured the field for large, underground pumps, hoists, and fans, but not for miscellaneous service. Mines have, and always will have, a complete distributing system for compressed air. In the future, they will also have distribution system for electric power.

Results of practical experience are outlined. Power cables should be of small capacity and all of the same size. Three separate types of protection should be used for overloads, short circuits, and grounds, respectively. Distribution is generally at 2300 volts but might, with advantage, be at 4000 volts, grounded neutral. Magnet switches have solved the problem of starting and controlling motors. Reduced voltage starting is undesirable. Sealed type bearings eliminate much bearing trouble. A new type of large hoist occupying the minimum of space is now being installed at the Park-Utah. The field of mechanical haulage is undeveloped, but conditions to be met are formulated. Mechanical loaders are beginning to receive serious attention.

* * * * *

THE lead-silver mining of Utah is a very important contributor of wealth to the State and presents several interesting and unique features as an industry using electric power, particularly in view of the fact that the use of power to replace manual labor and animal haulage is becoming of great importance in the reduction of cost of mining and the intensifying of production.

Any analytical study of present practise and the future trend of electrification must be based on a knowledge of the outstanding features of the industry, and in using the term *industry*, it is to be noted that this paper deals only with the operations of the large, established mining corporations.

The industry is essentially a combination of the processes of prospecting for new ore, extracting it, and marketing it. This calls for great skill in financing and in the broader functions of general management. The cost of borrowing money is high, the burden of taxation is beyond belief to those not acquainted with the facts, and the basic costs of labor and railroad rates are far above the average for other industries. These present handicaps may be viewed with optimism in the sense that there is great probability of their being decreased in the future, but they have a distinct bearing on the fundamentals of the mechanical operation of the properties.

Perhaps the most important result of these conditions is the necessity for speeding up the operations. The old idea that ore in the ground is the same as money in the bank no longer applies. The present value of a given probable tonnage is more than doubled if the rate of production is doubled. The human element—the psychology of the miners, bosses, and managers—also has a marked effect on the development of new mechanical methods.

Underground, conditions are fraught with physical hardship and danger hazards and the successful miners are of the hardy, adventurous, independent type, willing to go the limit and therefore rightly demand that all mechanical equipment shall endure the same hardships and hazards. There is also a feeling which may best be described as intense loyalty to all established and well-proved equipment, and this feeling of necessity carries with it an equally intense distrust of anything new.

One other feature of mining is of importance, and that is the enormous cost of providing space underground for the equipment and the much higher unit cost for larger excavations than for smaller ones. To meet the conditions above outlined, the electrical and mechanical equipment must be selected to comply with the following requirements:

1. Each and every part must be of sturdiest and most enduring design.

2. Maintenance and attention required must be reduced to a minimum.

3. The equipment must be compact and the dimensions of individual units must be suited to the sizes of shafts and tunnels through which they have to be transported.

4. Cost of installation must be minimized.

5. Equipment units must be standardized so that they may be moved from place to place and used under as wide a range of conditions as is practicable.

In the history of mining in this State, it is only a short time ago that all power used underground was transmitted by the mediums of compressed air or steam. Even at this time, there is no prospect of electric power supplanting compressed air for the operation of rock drills, and therefore there will always be a complete distributing system of compressed air available for the operation of small hoists, pumps, fans, conveyers, scrapers and loaders. For these items, the superiority of electric power is gradually proving itself and in due course of time, all the mines will have a complete distribution system of electric power.

For the larger underground power-using units, (pumps, hoists, and fans), electric power is a necessity. In the immediate future, there is going to be a rapid

1. Consulting Engineer, Salt Lake City, Utah.

To be presented at the Pacific Coast Convention of the A. I. E. E., at Salt Lake City, Utah, Sept. 6-9, 1926.

increase in the use of mechanical methods for underground handling of ore and waste. First, the equipment will be developed to use compressed air, but later on, it will be replaced by suitably designed electrical units.

The following is a review of present practise in the selection and use of electrical equipment for this industry.

Power is purchased at high voltage and transformed down to 2400 volts at outdoor substations of conventional design, with more liberal margins, however, on capacity and insulation. Such substations require no attendance during regular normal operation. The transmission of power from the 2400-volt bus bar to the points of use is by means of a number of small capacity cables, each feeding out through an oil circuit breaker with suitable time-limit overload protection. This development in the use of small capacity cables has in practise shown many advantages. In the earlier electrifications, cables as large as 250,000 cir. mils were used, but more recently, for the same amount of power, use has been made of three separate three-conductor cables of No. 4, B & S size. This particular size of conductor is well adapted as a standard for underground use, as its capacity is sufficient for the largest sized motor (300-h. p.) that is practicable underground, and its cost, installed, is less per unit of capacity than smaller or larger cables. With this subdivision of cables, it is permissible to use high grade rubber insulation without a lead sheath, but, of course, with a light metallic sheath for protective purposes. Such a cable has a low installation cost and a high salvage value.

The standardization of cable to a single size and type for all purposes is of great advantage to each individual mining property, in that it leads to great simplification in the protection of the cable system, and reduces the cost of the original installation and future changes and extensions. The effective space required for cables is less, in general, for a number of small cables than for one large cable.

With regard to protection of the cable system, separate methods are used for protection against overloads, short circuits and grounds. For overloads, the protective device is an oil circuit breaker with thermal type relays having thermal characteristics suited to the standard cable and therefore capable of carrying a very high overload current for a few seconds. For short-circuit protection, use is made of group circuit breakers with relays set for high current and short time interval. The grouping of the cables at a centralized underground switch is made to suit the particular conditions of the underground motor installations. For ground protection, a single ground-detector relay for each 2300-volt system operates an alarm, and the location of the defective insulation is determined by switching the various circuits. In a well installed system, such grounds are of rare occurrence, and if attended to at once, lead to no trouble whatever.

The voltage of motors is, in general, 2200 volts for 50-h. p. and larger sizes. It was the tendency in the past to shun such a high voltage—particularly for hoist motors—but now, with improvement in design of motors and the perfection of the magnet switch, the use of 2200-volt motors is preferable; in fact, if the manufacturing companies had not abandoned the old 4000-volt, grounded-neutral standard equipment at about the time that the mines were being electrified there would be many more mines in this district now using that voltage.

The selection of starting equipment is a matter of importance. Reduced-voltage starters are, in themselves, a source of trouble underground, and full-voltage starting is adopted wherever practicable. In all cases the starting should be by push button (unless it is automatic) in order to insure the switch being properly closed. For frequent operation, the hoist-type air-break contactor has proved superior to all others.

With regard to specific applications of motors for the surface plants, as well as underground, a few points are of interest.

For compressor drives, direct-connected, synchronous motors are standard practise and it is preferable to use automatic full-voltage starters with automatic air valves so that only one operation is necessary to put the compressor unit on the line. For surface hoists, the general practise is to use induction motors with full magnetic control. Ward Leonard control has many advantages, particularly in the matter of rapid and safe manipulation, but the additional cost is not always warranted. For underground hoists of large capacity, the limiting factor is cost of excavation for the hoisting equipment, head sheaves, and ropeways. An interesting solution of this problem has been worked out at the Park-Utah mine by the adoption of the Nordberg-Bollen design, in which a single head sheave functions as a hoist. In this installation, Ward Leonard control is used and the hoist, together with all the electrical equipment, is located in a rock chamber cut out above the top of the shaft. Complete remote control is used, with the operator on the level of the skip pocket.

For small and medium sized motors, the standard induction motor is about perfect if the bearings are properly maintained. The older designs of ring oiling bearings were not satisfactory, as they required too much attention and were liable to be robbed of oil for cleaning purposes. The newer types of sealed bearings and ball bearings are satisfactory.

The problem of underground haulage is far from a standardized solution. At present, the tendency is to use hand tramming or mule haulage whenever it is physically possible to handle the tonnage by those means. Practically no storage-battery locomotives are used, and trolley locomotives are used only when the weight of ore per train can be made as high as 30 tons. The standard gage is 18 in. and the standard

mine car, loaded, weighs about 3000 lb. A man can just tram a single car. A mule can pull seven or eight cars on the somewhat uneven grades of the smaller drifts. A four-ton trolley locomotive on the main transportation tunnels can handle about 30 cars. For complete electrification of the haulage, it is desirable to have two classes of locomotives, each operating, if so desired, as tandem units. The small size of 1½ tons would handle seven cars single, or 14 double, in the smaller drifts; and the four-ton size would handle 30 cars single, or, in a tandem unit, could handle 30 tunnel cars of about 2½ times the tonnage. It is to be noted that the cost of track facilities for handling trains is one of the big factors in the problem. It appears from some recent results that a double-trolley system is superior to storage batteries, and can be used where a single trolley is unsafe. It is important to note that with 1½-ton locomotives, it is not practicable to use the rail as a return for low-voltage operation because the surface cannot be kept clean enough.

In conclusion, it is to be observed that the methods in use are, of necessity, crude, but that the increasing use of electric power is having a very desired effect in demonstrating the advantage of more efficient operation and will lead to more complete electrification of all operations except rock drilling.

Iron and Steel Production

Annual Report of Committee on Applications to Iron and Steel Production*

F. B. CROSBY, Chairman

To the Board of Directors:

To anyone who has followed closely from its insignificant status at the beginning, on through the first and into the second quarter of this 20th century, the application of electricity in the iron and steel industry, the steady growth to its present gigantic proportions has always seemed inevitable, though none the less amazing.

In some respects, the year 1925-26 has seen all previous records broken in the rate of electrification. The applications of electric power have become so diversified that it renders entirely out of the question more than the briefest outline of outstanding features in the developments of the past year.

I. Generation of Power

The steam turbine continues to prove the most reliable of prime movers in the steel plant power station. With the increased economies in boiler room practise, with blast furnace gas as fuel, and the further use on the mills of cooling water from the condensers, the production cost per kw-hr. from the turbine driven generator, closely approaches that of the gas engine. Coal or oil can be used as auxiliary fuel supplementing the supply of blast furnace gas and thus avoiding delays which may arise due to shortage of gas during periods of castings or furnace repairs.

The thermal efficiency of the gas engine is very attractive and where an ample supply of blast furnace gas is available this prime mover finds warm support. Five new installations of gas-engine-driven blowers, and one gas-engine-driven generator are reported for the current year.

The ideal arrangement appears to be a combination of steam turbines, gas engines and purchased power, with dependence upon the gas engine and central station for the base load while the turbines float on the line carrying the peaks. Under these conditions a large block of power can be purchased at favorable rates owing to the comparatively low maximum demand charge, especially if hydropower happens to be available.

One steel company which is putting through a complete electrification program of old and new mills is building a modern power plant with two 12,500-kv-a., 6600-volt, 60-cycle, turbo generators to supply power for the plant. Steam will be obtained from blast furnace gas and powdered-coal-fired boilers designed for 300-lb. pressure at 180 deg. superheat.

There is no question but that blast furnace gas should be used as efficiently as possible and wherever possible, before any other fuel is considered. Considerable economies can yet be made in the use of gas for heating blast furnace stoves. This will leave more gas available for the generation of power, either through gas engines or boilers and turbines, for the production of steam for plant uses, or when mixed with coke-oven gas, for use in heating furnaces throughout the plant.

Coke-oven gas finds a ready application in practically every heating, reheating and annealing furnace operation in the plant, but where a large city offers a ready market, it is often necessary to restrict its use in the steel plant to effect an economic balance between city and plant consumption.

The steel industry is still looking to the central sta-

A. C. Cummins, A. G. Pierce, G. E. Stoltz,
W. C. Kennedy, A. G. Place, J. D. Wright.
F. O. Schnure.

Presented at the Annual Convention of the A. I. E. E., at White Sulphur Springs, June 21-25, 1926.

tions for an answer to the question of pulverized versus solid coal. In this field the opinion is prevalent that powdered fuel research and application are in the incubation stage and that developments in the near future may revolutionize present standards of boiler practise.

II. Distribution

Many steel plants have reached and passed the economic limit of 2200 volts for distribution. The large powers often required result in prohibitive current values at this voltage. This is reflected in excessive costs of protective oil switches and line losses even in the relatively short transmission distance from the load center to the numerous mill motors.

A distribution voltage of 6600 has become quite usual, so that only in the smaller plants, and in some cases where power is purchased, is 2200 volts standard. The increasing loads in the larger plants are taxing even the 6600-volt systems, but, so far, only one plant is reported as having main roll motors fed directly from a 13,200-volt system.

III. Main Roll Drive

Many of the mills laid out previous to the advent of the steel mill motor, now, each year, are reaching a point where, because of competition with recent equipment, it is necessary to throw them out or re-build them so far as possible along modern lines. The first consideration is usually the replacement of the original engine by a suitable motor and control.

One electrical manufacturer reports the sale of an aggregate of 33,270 h. p. of motors replacing engine drives during the past year. During this period the company has installed and placed in operation 31,000 h. p. (continuous rating) of reversing-mill motors and has taken orders for six additional reversing equipments aggregating 24,600 h. p. Three of these six units are replacing engine drives of existing mills, while two are for new mills which are to replace engine driven mills.

Notable among the reversing equipments installed during the year are two 7000-h.p. motors, the largest single armature machines thus far built for this service. An 8000-h. p. unit of slower speed but nearly 50 per cent larger in physical dimensions is, however, nearing completion in the factory.

Developments in the frequency converter type of alternating-current, adjustable speed drives provide for operation at constant torque above and below synchronism. This method of speed adjustment requires only two rotating machines,—the main motor and the frequency converter,—both on the same shaft. The slip energy of the induction motor is changed to line frequency in the frequency converter and returned to the line through speed adjusting transformers. Three units of this type, one of 770 h. p. and two of 1600 h. p. each, are now being built.

A 5000-h. p., 99-rev. per min., 60-cycle, induction motor built for a continuous billet mill drive is of interest particularly in that it is designed for 13,200-volt operation. Heretofore, except in one instance (see Report for 1925) main-roll motors have not been built for voltages above 6600 as it was thought that insulation troubles on higher potentials would be aggravated by the dirty atmosphere and conducting dust usually found in steel plants.

The necessity of maintaining constant speed relation between the several drives of modern tandem mills has brought about the development of a new method of control for compound wound, adjustable speed, direct current motors. This involves a series exciter and a variable potential field rheostat mechanically connected to the main shunt field rheostat, with resistance so proportioned that the series excitation is of the correct value to give very nearly zero speed regulation at any speed setting. This method of control is being applied to a 10-in., semi-continuous, merchant mill in three sections which are driven by 1000-, 1200- and 2000-h. p., d-c. motors respectively.

Another electrical manufacturer reports unprecedented activity in its steel mill business for the past year with an aggregate h. p. rating of mill motors sold from 1st June, 1925 to 1st May, 1926, of 102,910 h.p. This company also reports placing in operation a 4000-h. p. reversing drive in which the single motor is supplied from a fly-wheel motor generator consisting of two 750-volt generators permanently paralleled, a scheme first suggested by them in 1922 and now generally adopted.

This same electrical manufacturer also reports a new tonnage record for electrically-driven blooming mills made by a 40-in. mill, driven by one of its reverse equipments; namely 90,175 tons of ingots rolled in one month. A repeat order duplicating the electrical equipment was obtained for a 46-in. mill, using a motor rated 7000 h. p., 50 to 100 rev. per min.

Another of its installations of especial interest is a 9000-h. p. unity power factor, 107-rev. per min., 6600-volt, 25-cycle synchronous motor which, from the standpoint of continuous h. p. capacity, is the largest motor of any type used for industrial purposes in the United States or, so far as can be learned, in any other country. It is also notable in that it is the first really large synchronous motor to be used for driving a rolling mill. The motor may be started, stopped, or reversed from a master switch exactly the same as any other type of rolling mill motor. The Korndorfer system of control is used and the complete operation of starting on the low voltage tap of the auto-transformer, switching to a higher tap, applying field at the correct time, and throwing on the line, is taken care of automatically. In the design of the motor, particular attention has been given to obtaining very good starting torque characteristics. The excitation for the motor field is derived from a separate motor-driven exciter.

One of the best examples of motor drive for so-called tandem mills was put in operation about the first of the year. Practically every stand is driven by an individual direct-current motor, furnished with power from several synchronous motor-generator sets; a wide range of speeds is obtained by a combination of generator voltage and motor field control.

The aggregate capacity of the several motors driving this mill amounts to 15,850 h. p. (40 deg. cent.) The electrical apparatus is located in the best possible surroundings, emphasizing the growing importance which the mill operators are assigning to the electrical part of their equipment.

While the cost of such an elaborate drive is relatively high, the equipment is, on the whole, very economical; the flexibility and the wide speed range permits of rolling on this mill a great variety of products which would otherwise require at least two separate mills of a less flexible type.

The following tabulation includes only main mill motors on a continuous rated basis, in units above 300 h. p. as reported by the three principal electrical manufacturers in this country, up to 1st May, 1926.

	1923	1924	1925	1926
60-cycle	452840	478390	543440	586440
25-cycle	475825	490225	538450	582430
Direct-Current	299670	324860	430610	530060
	1228335	1293475	1512500	1698930

IV. Automatic Control

The year 1925 showed great activity in the application of automatic control to cranes and auxiliary mill machinery. Its dual functions of *control* and *protection* are now universally accepted so that there is now little opposition to its general use. Although there were no new developments of remarkable importance a most interesting feature was the rapidly increasing use of the inductive time element control system.

This system of control was commercially introduced in 1924 by one manufacturer and shortly afterwards a similar system was brought out by another. The essential features of these systems of control are: (1) -the short circuiting of accelerating resistance within a definite time, regardless of the load, and (2) the securing of a time interval purely by electro magnetic means. In the first system, the time interval is secured by making use of the transient voltage induced in a transformer or "inductor" due to changes in the motor current. In the second system, use is made of the slowly decreasing magnetism of shunt-wound relays when their coils are short circuited. Both systems fill a long felt need. Theoretically, current-limiting control provides a valuable protection to the motor. Practically, the protection actually afforded in many instances is almost nil since the current-limiting relays must be adjusted to start the motor under the heaviest load which may be encountered. With current-limiting control, therefore, the motor starts slowly under heavy load and quickly under light load, in either case subjecting the motor to excessive current. On the other hand, time-element control imposes excessive current on the motor only when the motor has an excessive load to accelerate and thus gives the motor much better average protection.

Although the larger portion of these installations has been for the control of mill tables and other auxiliary drives, a very considerable number has been installed for the control of open-hearth charging machines, soaking-pit cranes and standard cranes, particularly for the bridge motions. Installations of particular interest include a dynamic lowering controller for a bucket hoist and an ore-bridge trolley controller. Recent installations placed in control rooms entirely separated from the mill proper with control panels mounted in continuous switchboards, resistors mounted overhead in tiers on structural supports, with foot walks between, and with ample provision for ventilation, mark the growing appreciation of the fact that proper and substantial installation contributes probably as much as first class equipment to continuity and economy of operation.

A very interesting development of the past year which will surely have an important effect on crane control is the increasing use of roller bearings. One large installation has been made of cranes equipped throughout with roller bearings even including the sheave bearings in the hook block. An obvious effect of these anti-friction bearings is to increase the free running speed of bridges and trolleys and the light hook hoisting speeds. This imposes a greater responsibility than ever before on the control equipment to protect the motors and gearing in plugging and emphasizes the necessity for reliable brakes and limit switches for the hoists. Brakes on the trolley motors, hitherto rather unusual, would appear to be necessary on a trolley equipped with roller bearings. In some cases the hoist control will need to provide some means of limiting the light hook hoisting speed.

Automatic control of the electro-pneumatic type is being applied to the control of two 275-h. p., compound-wound motors in parallel for the drive of a large bloom shear. The cycle for this machine requires a complete operation in about six seconds and the pneumatically operated contactors of the large capacities involved are much faster and more positive in action than magnetic contactors of similar capacity. The electro-pneumatic contactors are assembled in steel frame work, and make a more conpact and rugged controller than the usual contactors mounted on slate or other insulating panels.

V. Automatic Sub-Stations

The use of automatically controlled sub-stations in steel plants has increased very greatly since the first installation in 1924. An installation recently put into

operation provides for the automatic control of two 1500-kw. synchronous motor generator sets and of twelve 4000-ampere, d-c. feeders. This automatic equipment is in a substation with several large reversing mill drives with an attendant always present, but it was felt that the more reliable operation was of sufficient value to warrant the installation of automatic equipment just the same. Several other installations are being made for the automatic control of motor generator sets and a-c. and d-c. feeders.

VI. Yard Electrification

The Diesel electric locomotive of which special mention was made in this report last year has grown rapidly in favor as experience has demonstrated its possibilities. Larger sizes up to 60 tons or more are now available and with their proved economy and reliability appear to have successfully solved the dangerous problems of third rail or overhead trolley in the steel plant.

VII. Illumination of Yards and Buildings

This past year has seen a marked impetus in the increasing recognition of the value of good lighting in mill buildings and yard. More attention has been given to the specific requirements of different kinds of mills and to the different operations within a given mill.

The kw-hrs. required for lighting range from 10 to 15 per cent of the total power load and is an appreciable item in the total cost. More efficient lighting units have been developed of larger wattage yielding more light per unit current consumption and, incidentally, requiring less time for cleaning.

VIII. Electric Heating

The use of electricity for heating is increasing rapidly in a great variety of applications. One instance of especial interest is the heating of ingot hot tops.

Early in 1925 an equipment was installed for heating the tops for ingots,—primarily of monel metal and nickel. Before using this equipment, 3800 lb. of metal was poured to obtain a 3000-lb. ingot, the waste averaging 20 per cent to 30 per cent. Now 3250 lb. of metal is poured and 85 per cent of the ingots are used with very little cropping while a large percentage of the remaining 15 per cent is worked into commercial products.

The electrical equipment consists of one 1800-kv-a., three-phase transformer designed to supply power to the ingot heating equipment and also to serve as a spare for a six-ton arc melting furnace. Other equipment consists of one 10-per cent, three-phase, air core reactor for use in the 2200-volt circuit, instrument and control panel; also six automatic, single-phase, electrode regulating equipments for controlling the input to the arcs used to heat the top of the ingot.

IX. Electric Furnace

Last December, several units of the first commercial installation of Northrup induction furnaces operating at 480 cycles were put in operation. This particular installation was made for melting nickel silver and similar alloys, but these equipments have many possibilities in the heating and melting of ferrous metals and alloys, several applications being under consideration at present.

The initial installation consists of two motor-generator sets, each delivering 600-kw., single-phase, 1875 volts, 480 cycles, to six Northrup high-frequency furnaces, each generator being driven by a 3-phase, 60-cycle, 2300-volt synchronous motor, with direct connected exciter. To compensate for the low power factor and obtain best circuit conditions, a bank of capacitors is included with each furnace.

Last fall, the equipment for the first three-voltage-control arc melting furnaces was sold. These equipments are used with six-ton, three-electrode furnaces, one originally installed with a 1200-kv-a. bank of transformers and the two others with a 1500-kv-a. bank of transformers.

Each new equipment consists of a 2550-kv-a. bank of transformers which will deliver full output at 165, 156 or 147 volts and a lower capacity at 138, 120, 95, 85, 80 or 70 volts. Air core reactors of 25 per cent capacity for connection in the 11,500-volt circuit, together with suitable switching equipment, were also included.

The melter has a choice of several voltages to start the heating, probably using 2550 kv-a. at 165 or 156 volts, 2400 kv-a. at 138 for the intermediate voltage and a still lower kv-a. at the refining voltage,—probably 85 or 90 volts, depending upon the furnace equipments.

Marked economies are effected in furnace operation, especially from the standpoint of the life of the side walls and roof, together with possible reduction in electrode consumption.

In conclusion, I wish to give full credit to the members of this committee for their effort as individuals in gathering the data which forms this report.

MESSAGES FOR MISSOURI

A short-wave set, operating on four to eight meters, is aboard. It is to be used to send out messages that can be picked up by amateurs in case of necessity at great distances. Some operator in Missouri or deep in the interior of Europe may hear this set during the Fonck flight and relay the message by wire to his government if the call is an S. O. S.

Both these sets are operated on storage batteries that are charged by two tiny generators. Each generator is driven by a fan with four-inch blades extending out into the "air slip" or stream of air that passes the plane during flight.—*Elec. Rev.*, July 25.

Engineering Education—Its History and Prospects

BY HENRY H. HENLINE*

Associate, A. I. E. E.

Synopsis.—*A brief history of the development of engineering education in the United States and a consideration of the usual type of curriculum in particular branches of engineering are followed by reasons for the development of a new type of curriculum and a discussion of its principal characteristics.*

The recently adopted curriculum leading to the degree of Bachelor of Arts in Engineering at Stanford University is given in detail. The ideals discussed in the paper are emphasized by a few selected quotations from statements of leading executives and teachers.

IN order to gain a true perspective of the subject of engineering education, one must consider its early history in the United States. The first American colonies were forced by Parliament to limit their production to agriculture and raw materials, and when they made the non-importation agreement in 1774, there appeared an urgent need for skilled workers in all mechanic arts. This situation was relieved by the formation of societies which exerted all possible effort to encourage the useful arts and by prizes offered "for the best achievement in every essential line of industry." After the war, similar activities were made necessary by the fact that England attempted to stop the development of industries by underselling methods.

During the years immediately following the war, many engineering developments were made, notably:

1787 —First flour mill machinery.
1790 —First textile mill driven by water power
1793 —Invention of the cotton gin
1801 —First high-pressure steam engine
1801 —High-capacity double steam pump
1807 —First steamboat
1786-93—Several canals begun

The war of 1812 again made it necessary that American industries manufacture all necessities, and this, together with the fact that much of the soil was becoming exhausted, produced a very urgent demand for scientific information which would lead to greater production in both agriculture and manufacturing.

As a result of this demand, the Rensselaer Polytechnic Institute was established at Troy, New York, in 1824. The curriculum, which was one year in length, contained a great variety of subjects. During the last nine weeks of the year, a study was made of the practical applications of the sciences previously studied. In 1835, instruction in civil engineering was added and students who completed the new curriculum were awarded the degree of Civil Engineer. Following a thorough study of instruction in French technical schools, the Rensselaer curriculum was lengthened in 1849, to three years. The first half of the curriculum was planned so as to lay a general foundation for all engineering, and the last half contained courses designed to allow for specialization in some particular branch.

In much of the early demand for such schools, the need for training as an aid to industrial production was very strongly emphasized, but there was also a rather insistent demand for instruction in science as part of a liberal education.

The Lawrence Scientific School at Harvard and the Sheffield Scientific School at Yale were established in 1847. At the same time, the University of Michigan decided to give a course in civil engineering. No other engineering schools were established before the Civil War[1].

One of the most significant steps ever taken in providing for higher education was the passage by Congress of the Morrill Act in 1862. By this Act, the National Government presented to each State in the Union 30,000 acres of public land for each senator and representative in Congress. The purposes as stated in the Act were, " . . . the endowment, support, and maintenance of at least one college, whose leading object shall be, without excluding other scientific and classical studies, and including military tactics, to teach such branches of learning as are related to agriculture and the mechanical arts, . . . in order to promote the liberal and practical education of the industrial classes in the several pursuits and professions of life."[2]

The results of this Act were extremely gratifying to those who had been appealing for more technical schools. In 1870 there were seventeen such schools as compared with the four established before 1862. The number continued to increase very rapidly, and there were forty-one in 1871, seventy in 1872, and eighty-five in 1880[1]. At the present time there are approximately 130 engineering schools of college grade in the United States.

A number of these early schools were called industrial universities because the greatest demands for them had been based on industrial needs. The idea that manual labor occupied an important place in their training soon became so widespread that many objections to

*Associate Professor of Electrical Engineering, Stanford University.

Presented before San Francisco Section, April 23, 1926, and to be presented at the Pacific Coast Convention of the A. I. E. E., Salt Lake City, Utah, Sept. 6-9, 1926.

1. For references see end of paper.

such names arose, and changes were made. For instance, the Illinois Industrial University became the University of Illinois in 1885.[3]

Although the first schools offered civil engineering only, the curricula were soon extended to include several branches of science and engineering. The Massachusetts Institute of Technology, which was established in 1865, offered six four-year curricula as follows:

Civil Engineering
Mechanical Engineering
Mining Engineering
Practical Chemistry
Architecture
General Science

The first curricula of the Illinois Industrial University, established in 1867, were:[4]

Agriculture
Polytechnic—including
  Mechanical Science and Art
  Civil Engineering
  Mining and Metallurgy
  Architecture and Fine Arts
Military
Chemistry
Natural Science

Four years were required for the completion of each. The above examples are fairly representative of curricula offered by all of the early technical schools. The general plan in all cases was to provide training in mathematics, drawing, physics, chemistry, etc., in the earlier parts of the curricula, and to have the work in applied science follow such training according to the plan used in French schools. English and foreign languages were usually included in the curricula.

The number of curricula in engineering increased very rapidly with the extensive development which occurred in the applications of engineering knowledge of all kinds. There are now available curricula in about forty branches of engineering, including aeronautical, agricultural, architectural, automotive, ceramic, chemical, civil, electrical, marine, mechanical, metallurgical, mining, sanitary, etc.

The great increase in the number of curricula offered has been accompanied by numerous changes in their content. The chief tendency has been to include more technical subjects to keep pace with the phenomenal expansion of engineering activities. This expansion itself has made even more necessary than before a very thorough education in the fundamental subjects. Hence, serious overcrowding has resulted.

This has been relieved to some extent in many schools by the growth, from each curriculum in a particular branch of engineering, of several curricula covering the various sub-specialties. This process is only a partial remedy, however, because some of the sub-specialties have grown into branches of great magnitude, and the growth has by no means ended.

The type of curriculum now in most general use is one leading to a Bachelor's Degree in a particular branch of engineering (any one of approximately forty) at the end of four years. Such a curriculum contains a common core of subjects required of all engineering students, and consisting of the following groups of subjects:[5]

Science: Mathematics, chemistry, physics, mechanics
Mechanics Arts: Drawing and shop work
Humanities: English, foreign language, economics, etc.

These foundation courses are followed by the various engineering subjects considered essential in the specialized curricula. As a general average, the student's time during the four years is distributed about as follows[6]:

Languages and humanities........... 19 per cent
Mathematics and sciences............ 29 per cent
Engineering subjects................. 52 per cent

Since the languages and humanities group receives only 20 per cent of the time, and English and foreign languages are usually strongly emphasized, little or no time is spent on certain very important subjects such as biology, economics, geology, history, political science, psychology, business law, etc.

The group of subjects including mathematics and the sciences, principally chemistry and physics, receives strong emphasis in nearly all curricula because these subjects really constitute the foundation of all engineering. These, together with the group mentioned above, are usually given in the first two years.

Drawing and shop work are usually considered very essential subjects, and receive their proper proportion of time. The value of shop work, however, has been seriously questioned during the past few years. Many experiments in the handling of such courses have been tried. In a few schools, the university shops have been operated on a production basis in order that students might have experience as production managers, foremen, machine operators, etc., and thus receive a training designed to enable them to understand shop operations of all kinds. Others have developed cooperative courses with neighboring industries so that shop training as well as many other kinds of training can be obtained under practical industrial conditions. Throughout the period covered by these experiments there has been a considerable strength of opinion that shop work is being allowed to take time which should be allotted to other subjects, and the reasons why all engineering students should develop facility in handling tools have not been clearly shown.

Following these two years of preparation, the latter half of the curriculum is usually nearly filled with engineering subjects. This makes it necessary that each student decide early in his university career which one of the many branches of engineering he is most interested in and best fitted for. The time at which such a decision must be made if he is to graduate with his class depends upon the school chosen. In

some it is as early as the beginning of the first year. A large number require this decision at the beginning of the second year, and about one-fourth permit it to be made as late as the beginning of the third year. Very few schools permit greater delay[7].

During the work of the last two years, there is usually a considerable number of courses dealing with the various phases of the specialty chosen. There are also courses in related branches of engineering. Thus a student in civil engineering is usually required to take a course or two in electrical and mechanical engineering, and a student in electrical or mechanical engineering usually takes surveying in the civil engineering department. However, the major portion of the time is spent on the subjects closely related to that chosen for specialization.

In connection with the very thorough investigation of engineering education now being conducted by the Society for the Promotion of Engineering Education, many questionnaires have been used to secure information on all phases of education and related matters. One such questionnaire now being circulated gives ten divisions of electrical engineering, and asks which ones are considered so important that special curricula in them should be offered.

A serious result of the tendency to keep adding technical courses to curricula which are already completely filled is found in many schools in which the requirements for graduation in engineering include a considerable number of units more than required for graduation in other curricula. It is quite common to find this situation made more serious by the fact that there are few if any courses in subjects which prepare men for dealing with people, namely, citizenship, economics, political science, etc., or subjects which provide any cultural value. Many such curricula are extremely rigid, and allow almost no choice of subjects. Therefore, students are expected to follow a certain list of courses with very little thought as to their own interests.

The established order of subjects in most curricula, *i. e.*, languages, chemistry, physics, mathematics, mechanics, drawing, and shop work in the first two years, and engineering subjects in the last two, is often severely criticized because practical applications always follow theoretical principles. Another result of this order of subjects is that the students have very little contact with engineering or engineering faculty members during the first two years. Several institutions have tried the experiment of giving engineering problems throughout the first year. The success has apparently been great, as such work stimulates the students' interest and assists in making the final decision as to the special branch of engineering in which they wish to specialize. However, it seems to be impossible to coordinate theory and practise in a curriculum in such a manner as to meet all objections. Certain fundamental subjects must precede the more advanced subjects, and no Utopian scheme which includes all subjects mixed in proper proportions and arranged in ideal order has been proposed. It seems that the students of a worth while type should be able to maintain their interest through two years of work in fundamental subjects. It is a serious question whether one who cannot do so does not more properly belong in a trade school than in a university.

The investigation now being conducted has shown that about 62 per cent of the students admitted to engineering curricula fail to graduate, and the elimination occurs largely in the first two years[8]. This fact is causing a serious consideration of the factors involved with the hope that the mortality can be reduced. It has been suggested that the adoption of two-year curricula leading to a certificate or diploma, and preparing students definitely for certain kinds of technical employment, might be a satisfactory solution. There are a number of very serious objections to this procedure. Such a two-year curriculum would not provide the most suitable first two years' training for those who wish to complete a four-year curriculum, and it would be difficult or impossible for most institutions to provide facilities and personnel to handle both classes of students. The most serious objection, however, is the fact that this would definitely lead many able men into mediocre technical positions where their future progress would be slow. The failure of a student in mathematics or some of the other subjects placed early in the engineering curricula does perhaps indicate that he cannot be successful in the higher types of technical work, but it by no means indicates that he cannot become a successful man in the business or management side of engineering.

It seems obvious that the greatest need is for some means of determining what each student is best fitted for and the type of intellectual effort in which he is most interested. If each could receive expert assistance in the determination of his strongest natural aptitudes, the number of such eliminations would be greatly reduced. Many men now turned out as failures in the engineering curricula would be highly successful in some field of human endeavor, and this would be a far more satisfactory outcome than would be obtained by guiding all such men into mediocre technical positions.

To sum up the characteristics of most of the curricula now in effect: They are too rigid in that little allowance is made for the interests or initiative of the students when a decision has been made to specialize in a particular branch. This decision must, in most cases, be made before students are mature enough or have had sufficient experience to decide wisely. They devote too small an amount of time to broad education and too much to narrow specialized training.

A number of universities have developed five- or six-year curricula in order that more general subjects might be included without omitting the engineering courses which are considered necessary. In several

cases no degree is received until the completion of the entire five- or six-year period.

The cooperative type of education has some well recognized advantages in schools of all grades. The Massachusetts Institute of Technology and the University of Cincinnati are the two outstanding examples in the engineering field. At the former, the cooperative curriculum is five years in length. The first two years are the same as the usual electrical engineering curriculum, but during the last three years, alternate terms, including summer terms, are spent in the industries. The fifth year is devoted to graduate work and research in both the Institute and the companies. Each man has a choice of manufacturing and utility companies, but works in the same company during the three years. His compensation averages about $1500 for this period.[9]

The ideas expressed below, regarding some of the ideals of engineering education, are not those of any one man alone, but represent the aggregate opinion of the author and others. An earnest effort has been made to include the best thought on the subject.

The requirements of engineering education could be determined more definitely if there were a generally accepted definition of engineering. The following definition was given in his president's address in 1908, by Past-President Stott:

> "Engineering—The art of organizing and directing men, and of controlling the forces and materials of nature for the benefit of the human race."[10]

The first part of this definition shows that an important part of education consists of subjects which will enable those men who will become executives to develop more rapidly.

Probably a large majority of undergraduates in engineering schools believe they will be engaged for many years in work primarily technical. The results of the S. P. E. E. investigation show that of the three most recent classes 71 per cent are in work primarily technical, while more than 70 per cent of those in classes out fifteen years or more are in work primarily administrative.[8] Such records certainly indicate clearly that a broad education is more important than training in technical subjects. In 1916 a circular letter was sent to thirty thousand members of the four large engineering societies requesting them to number six groups of qualities headed Character, Judgment, Efficiency, Understanding of Men, Knowledge, and Technique, in the order of importance given them in accounting for engineering success and in considering young men for employment. Of the seven thousand replies received, 94.5 per cent placed the Character group at the top of the list, and about the same number placed Technique at the bottom[11]. Success in engineering obviously depends upon many factors besides technical knowledge and skill. The really successful engineer must be able to coordinate theory, practise, and economics, and to handle men. As shown above, most of the engineering curricula now in effect were planned in the earlier years of engineering education, and the changes made since have consisted principally in the addition of more technical courses. Most of the curricula furnish excellent preparation for certain types of work into which some of the graduates enter. On account of the extremely rapid progress that has been made in many branches of engineering during the past few years, the applications of engineering knowledge are now so many and so diversified in character that any curriculum designed to meet directly certain needs in industry may indeed prepare men in a most excellent manner for those needs, but fail utterly to prepare them for a great range of engineering problems, both executive and technical, which all graduates will be called upon to solve.

The very strong and growing tendency to choose executives from men with engineering training is a force which must be reckoned with. Problems which executives meet are becoming so complex and so closely associated with fundamentals of engineering that some technical knowledge is essential. No one believes the schools can train executives, as ability in this direction depends primarily upon inherent characteristics. However, if engineering graduates are to receive their fair share of such positions, they must be given the broad, general foundation which is absolutely essential.

During the past few years many high executives in some of our largest industries have advocated a broad type of training for engineers. In employing recent graduates, they prefer to obtain men who have had a thorough training in fundamentals and who have not specialized in some small branch of one of the principal types of engineering.

What, then, are the principal characteristics of a satisfactory engineering curriculum? The answer to this question depends upon the types of activity for which the schools attempt to prepare men. In the present stage of development, it seems necessary to recognize the needs of two general groups of students, *viz.*, those who expect to spend their lives in highly technical design or research, and those who will be engaged in commercial, industrial, or administrative phases of engineering. Both groups need a broad foundation consisting of such subjects as English, economics, biology, geology, history, business law, political science, etc., and thorough training in chemistry, physics, mathematics, mechanics, and other subjects which make up the heart of engineering. Such training should be mixed with and followed by courses giving the fundamentals of all of the principal branches of engineering, and there should be a reasonable amount of time available for elective subjects. Thus far there is no serious difference between the wishes of executives in industry and teachers of engineering. It therefore seems that the chief cause of argument is the relatively small group of men who will engage in research and other highly technical phases of engineering. This group must have better oppor-

tunities for the development of research ability and for specialized study than can be provided in any four-year curriculum which contains sufficient training in fundamentals. It seems clear that the usual type of four-year curriculum fails to meet the needs of all except those who wish to remain in the specialized divisions of engineering which do not require either a very broad training or an advanced technical education.

Many professional engineers believe a university curriculum should provide broad and thorough training in the fundamentals of engineering, and that considerable emphasis should be placed upon humanistic subjects such as English, economics, sociology, history, etc., not merely on account of their usefulness to the engineer, but also on account of their broadening influence[12]. Another phase of the investigation of engineering education now being conducted has developed the strength of this demand. The opinions of 1931 graduates of the classes of 1919, 1914, 1909, 1904, 1899, 1894, 1889, and 1884 on the principal objectives of engineering education are as follows[13]:

	No.	Per cent
To train broadly for the general needs of the industry	398	20.6
To train for specific needs of specialized divisions of engineering practise	229	11.9
To provide the former type of training for the majority, but provide the latter type for those who desire to spend the additional time required	1304	67.5

The enormous physical plant which has been built up during the last few decades has produced problems never thought of in the early engineering curricula. The country-wide net-words of railroad, telephone, power, and radio systems have brought with them a host of problems in all branches of engineering, ranging by degrees from management, with all of its extremely complicated personnel and technical questions, on the one side to the most advanced scientific research, with its exacting demands in mathematics and the sciences, on the other. The size of the field in which a young engineer finds himself shows clearly the futility of any four-year curriculum of a specialized nature. The only adequate preparedness for such a field is a broad education in the humanities, fundamental sciences, and engineering fundamentals.

The results of the investigation indicate that the most serious criticism of engineering education arises from the lack of training in business and economics[14]. The fact that success depends largely upon a good understanding of those subjects seems to be very generally recognized.

It has been said that engineering graduates of the past have risen to high executive positions and that this indicates that no great changes in curricula are necessary. Many of the questionnaires covering various phases of the investigation contain replies which show that in general engineering alumni think the curricula were not seriously deficient in any important respects except in the lack of business and economics. It must be remembered, however, that the questionnaires were planned to bring out the facts regarding existing curricula, and those who answered them were given no real opportunity to express their opinions of the recent movement toward more liberal engineering curricula.

In 1920 Stanford University put into effect the Lower Division plan which replaces the major department system during the first two years. The principal object is to require more training in fundamental subjects. During this period, the students are registered under the supervision of the Lower Division Committee which is appointed by the President. Each is required to take certain subjects and to choose other subjects from specified groups. Some of the requirements can be met by certain high school subjects. The requirements do not completely fill the first two years, and the remainder of the time can be devoted to electives. The following is a brief summary of the requirements[15]:

Group Requirements

I	Languages and literature and formative art	18 units
II	Natural sciences and mathematics	18 "
III	Social sciences	18 "

Subject Requirements

English composition	6 "
Foreign language	22 units in one, or 15 units in each of two foreign languages
May be anticipated in high school in whole or in part.	
Biological science	9 units
Physics or chemistry	9 "
One of the sciences may be anticipated in the high school.	
American history	9 units
General history	9 "
One of the history requirements may be anticipated in the high school.	
Citizenship	12 units

At the beginning of any quarter, a Lower Division student may designate the department in which he expects to register during the last two years. Those who thus make a tentative choice of major subject are then advised to consult the department regarding the most suitable courses to take as electives during the first two years.

In the autumn of 1924, the President appointed a special committee made up of representatives of all of the engineering departments, and requested that the various phases of work in engineering be considered and recommendations be made to him. That committee presented its report in March 1925. In this it recommended that a School of Engineering be organized, that a more general type of engineering curriculum leading to the degree of A. B. in Engineering be adopted, that the department curricula, with certain modifications, be retained at the option of the departments, and that two-year graduate curricula leading to the degree of Engineer be adopted by those departments

which had been requiring only one year. The recommendations were adopted by the University, and Professor Theodore J. Hoover, Executive Head of the Department of Mining and Metallurgy, was appointed Dean. Committees were appointed last October, and the registration of students in the tentative form of general engineering curriculum was begun in January 1926.

A revised form of curriculum has recently been adopted by the Faculty of the School of Engineering, and a copy of it is given below.

FOUR-YEAR CURRICULUM LEADING TO THE DEGREE OF BACHELOR OF ARTS IN ENGINEERING**

FIRST YEAR, TOTAL UNITS, 44

Subject	Course No.	Autumn	Winter	Spring
Foreign Language		3	3	3
Linear Drawing and Lettering	C. E. 1, 2	..	1	1
Chemistry		4	4	4
Co-ordinate Geometry	Math. 10, 11	3	3	..
Calculus	Math. 21	..	..	3
Citizenship	Citizenship 1-3	4	4	4
Total		14	15	15

SECOND YEAR, TOTAL UNITS, 46

Subject	Course No.	Autumn	Winter	Spring
English Composition	Engl. 2a, 2b	3	..	3
Freehand Drawing	M. E. 11	3	..	..
Calculus	Math. 22, 23	3	3	..
Heat and Electricity	Physics 13, 14	..	4	4
Mechanic Arts	M. E. 1, 2 or 3	*..	2	2
Descriptive Geometry	M. E. 10	..	4	..
History		3	3	3
Extemporaneous Speaking	Engl. 7	3	..	..
Elementary Machine Drawing	M. E. 12	..	..	3
Total		15	16	15

THIRD YEAR, TOTAL UNITS, 45

Subject	Course No.	Autumn	Winter	Spring
Theoretical Mechanics	C. E. 30, 31	5	5	..
Hydraulics	C. E. 106	..	..	5
Surveying	C. E. 20	5	..	..
Engineering Geology	Geol. 1a	5	..	..
Electricity in Engineering	E. E. 102, 103	..	3	3
Elementary Accounting	Econ. 3	..	5	..
Principles of Mining	M. & M. 101	..	..	5
Electives		..	2	2
Total		15	15	15

FOURTH YEAR, TOTAL UNITS, 45

Subject	Course No.	Autumn	Winter	Spring
Mechanics of Materials	C. E. 110	5	..	..
Pyrometallurgy of Iron and Steel	M. & M. 105	..	3	..
Exposition	Engl. 131	4	..	..
Business Law	Law 100	4	..	..
{ Prime Movers	M. E. 123		5 or	.. }
or Elementary Machine Design	M. E. 113	..	4	.. }
Engineering Economics	C. E. 130	..	..	3
Human Relations in Business		..	3	3
Electives		2	4 or 5	9
Total		15	15	15

*All these Mechanic Arts Courses are given in the Autumn, Winter, and Spring Quarters. Any two courses may be chosen by the student, limited only by the capacity of the laboratories. Although scheduled for the Winter and Spring Quarters, sufficient registration is desired for the Autumn Quarter to make operation of all three laboratories possible.

**Since the presentation of this paper before the San Francisco Section, minor corrections have been made in this schedule to place it in complete accord with the curriculum appearing in the Stanford University Announcement of Courses for 1926-27.

This curriculum is founded on the belief of many that any considerable amount of specialization in engineering subjects during a four-year course is undesirable. All students should have a good foundation in general or cultural subjects. In addition to this, engineering students must have rather extensive training in chemistry, physics, and mathematics. There is a number of subjects such as mechanics, hydraulics, surveying, geology, business law, etc., which all engineering students should take. Finally, a young man who hopes to become a broad minded and well balanced engineer must have some knowledge of the contents of all of the principal branches of engineering, first, in order that he may be able to choose more intelligently the branch he wishes to follow as a specialty, and, second, in order that he may be able to consider all problems in their proper relation to the whole field of engineering. It is desirable also that such a curriculum allow a reasonable amount of time for elective subjects.

The above curriculum is not considered final. It is hoped that improvements can often be made in it. However, we believe it does follow closely the ideals expressed above.

The decision has recently been reached that the A. B. degree will not be awarded in the separate branches of engineering at Stanford after 1929.

The graduate study in each department is to continue over a two-year period leading to the degree of Engineer in the various branches. It is firmly believed that students who complete the six years will be very much better prepared for their life work than are those who take a more specialized course for four years and then one year of graduate work.

The question will often arise as to whether students who complete the four-year curriculum only will be prepared to begin work in certain engineering organizations. It is true that they will not be as well prepared in a certain few special phases of engineering as would the graduates of a more specialized curriculum. However, they will have a much wider range of choice, and need not feel limited to only a few specialties. If they devote their electives to carefully chosen courses, there need be no feeling that they are not prepared to become immediately useful. Future progress should be materially faster due to the broad foundation.

A few quotations from statements of leading executives and engineers will emphasize some of the statements made above.

SECRETARY OF COMMERCE HERBERT C. HOOVER[16]

"There is somewhere to be found a plan of individualism and associational activities that will preserve the initiative, the inventiveness, the individual, the character of man and yet will enable us to socially and economically synchronize this gigantic machine that we have built out of applied sciences. Now, there is no one who could make a better contribution to this than the engineer, but to make that contribution our engineers in the future have got to have a broader and stronger place in our world affairs than they have today. We cannot be turning men out of our universities as we are in many cases today purely mechan-

ical machines devoted to some theory built on applied sciences. If the engineer is going to take his part in this community, is going to give expression to those things that he can express best, he must start with a sense of his public obligations as well as his professional knowledge."

* * * * * * *

* * * "but we had better reduce the volume of science and applied science we are pouring into our young men in order to make room for some stimulation of their public relationships, some realization of their public obligations."

F. C. Pratt, Vice-Pres., General Electric Co.[17]

"Voicing my own opinion on this subject, we are not looking to the colleges and technical schools to turn out finished engineers, but we do look to them for a steadily increasing supply of young men who have been thoroughly trained in the fundamental theories of the mathematical and physical sciences, and to the fullest practicable extent in economics and in what are commonly called cultural studies. We believe that, with this ground-work thoroughly prepared, the large industries are in a particularly favorable position to offer exceptional opportunities to young men for gaining practical knowledge and experience along special lines.

"In this connection, I wish to make it quite clear that in the foregoing remarks I am not including those exceptional students who by natural qualifications and inclinations are prepared to pursue post graduate studies in theoretical work in any branch of science or engineering which contributes to the industry."

F. C. Pratt[18]

"My observations also leads me to the conclusion that the percentage of those who fail to attain a reasonable degree of success is greater in the group of men of mediocre ability but narrowly specialized education than in almost any other group coming within my knowledge."

Professor Edward Bennett, University of Wisconsin[19]

"One of the most gratifying developments of recent years has been the recognition on the part of the engineering industries that they do not wish to have the engineering colleges train men for immediate service in their specific fields."

Dean F. L. Bishop, University of Pittsburgh[20]

"There are two factors which enter fundamentally into the life of an engineering student. One is education, the other is training. In the very early days of the engineering school, education was the controlling idea; later, training or specialization became the controlling factor. In other words, we shaped our courses, modified our curriculum, and selected our teachers with the sole purpose of graduating professionally trained engineers.

"The reaction soon became evident. The cry went up that the engineer, although thoroughly trained, was narrowly educated. He lacked the proper perspective of life. He was unable to grasp the economic principles underlying great problems. He was too intent upon design and the solution of specific problems.

* * * * * * *

"We must look forward to the time when engineering schools will consider themselves as educating a large body of men who will become effective managers of the industries and who will exert, through their education and training, an important influence on the political and social side of the community.

"If our engineering schools will look upon the education and the training of this large mass of men as their primary object, and delay the specialization and technical training to additional years in the schools or industries, our instruction will be changed to meet this demand so that the emphasis will be placed more on education and less on specilization. Our teachers will not be such highly specialized technical experts but that they will be broadminded educators. The public will show an increasing confidence in our graduates because they will be educated as well as trained."

Dr. F. B. Jewett, Vice-Pres., American Telephone and Telegraph Company[21]

"Consequently I am interested in having those young men who come to us and who are going to be the leaders of our business of the future well grounded in the sciences. First, because we need them in the technical side of our business, and second, because I believe we are going to need them in a larger measure as the recruiting source for the executive directors of our business in years to come."

John Mills, Director of Publication, Bell Telephone Laboratories, Inc.[22]

"After we have answered these intermediate questions, we shall probably agree that we turn to the colleges in the hope of obtaining men of good mental ability and personality, who have acquired habits of thought and study which will enable them to see broadly the business and technical problems of the future, to analyze the factors involved, to arrive objectively and without prejudice at solutions, and, through personality and executive ability give to those solutions weight and effectiveness. We look, I believe, for trained brains in vigorous bodies with pleasant but dynamic personalities; men who may make creative contributions to our respective businesses or arts and, in a sufficient number of cases, develop as capable executives."

Dr. M. I. Pupin, President, A. I. E. E.[23]

"Nothing resists a change so obstinately as the mental attitude of man. The history of science from Archimedes to Newton offers many illustrations of this well-known fact. The change in the mental attitude of our age is one of the greatest achievements of our intellectual renaissance. Less than two generations ago, educational training was expected by many to operate like a penny-in-the-slot machine; that is, learn your lesson and convert your learning into cash without much delay. The so-called practical man who managed our American industries was at that time an ardent advocate of this utilitarian theory. He worshipped the art of making a living. Franklin and Lincoln, my patron saints, had no sympathy with this theory. The art of making a living was not the determining factor in their schooling, but the art of making life worth living was everything to them. They would find no fault with the American college because its diploma does not testify that college graduates are loaded with a knowledge of the art of making a living, provided, however, that they carry with them some definite ideas about the art of making life worth living, not only their own individual life, but also the life of our nation. The expansion of these ideas is the gospel of the American university."

Instruments and Measurements

Report of Committee on Instruments and Measurements*

A. E. KNOWLTON, Chairman

To the Board of Directors:

The Committee on Instruments and Measurements undertook to continue this year two of the studies begun in 1924 and to start a third major study.

POWER AND ENERGY MEASUREMENT

One of the first two was that of the measurement of energy and power under the following conditions:

1. A study of methods of measurement of variable power, with particular regard to cases of commercial importance, such as efficiency tests on large machines.
2. A study of methods of measurement of energy in large blocks where the high value of the product makes every practicable improvement of the method desirable.

The subcommittee originally consisted of H. B. Brooks, Chairman, F. V. Magalhaes, and J. R. Craighead; because of weight of other business, Mr. Brooks resigned as chairman and Mr. Craighead was appointed chairman, and G. A. Sawin added to the committee. It was decided that, in both problems, great advantage could be secured by improvement in watthour meters and the subcommittee took the first steps toward accumulating data on the present performance of watthour meters as a basis upon which to proceed. The presentation in February, 1925, of the paper by Messrs. Kinnard and Faus on *Temperature Errors in Induction Watthour Meters* indicated such an advance in the field of watthour meters that it was considered unnecessary to accumulate the data referred to above; this branch of the work was dropped, therefore, because that and other work now in progress makes it seem probable that meters of substantially improved accuracy, particularly with regard to errors with varying temperature, would be available.

In connection with the further study of the first problem, the paper by Mr. E. S. Lee, presented in May 1925, entitled *Measurement of Electrical Output of Large A-C. Generators*, covered to a satisfactory degree the necessary details of application of indicating instruments to the testing of variable power.

In the measurement of energy in large blocks, present commercial methods require the use of instrument transformers and watthour meters. Therefore, the subcommittee has prepared the following short discussion of methods and devices in use:

This discussion refers to the measurement of energy on three-phase circuits at large supply or interchange points, where the value of the energy is large enough to justify any reasonable complication or expense to improve the accuracy and certainty of measurement.

When power is measured in large blocks, the current and voltage are practically always of such values as to require instrument transformers, both for convenience in application to meters and instruments and for protection of operators. The systems are usually three-phase. Grounding conditions of the systems vary, but for metering purposes may be classified in three groups:

1. Ungrounded.
2. Having one or more grounds on only one side of the metering point.
3. Having grounds on both sides of the metering point or a fourth wire so that there is the possibility of currents passing the metering point outside the three-line conductors.

E. D. Doyle,	W. J. Mowbray,	Roy Wilkins.

Presented at the Annual Convention of the A. I. E. E. at White Sulphur Springs, June 21-25, 1926.

1. Ungrounded Systems. The usual form of metering is by the use of two potential and two current transformers with a polyphase meter shown in Fig. 1. The advantages lie in the fact that there are only four transformers and one meter to care for, and that the meter will rotate forward under all conditions where the energy flow is in a given direction. The disadvantages lie in the necessity of having elements with closely similar characteristics and with negligible interference, and in the fact that the power factor under which the elements actually operate differs from the line power factor due to the use of voltages which in a balanced circuit are dephased 30 deg., one in the lagging and one in the leading direction from the position representing the true power factor of the three-phase circuit. For this use, therefore, the meter selected should have:

a. Close balance of elements and negligible interference between elements.

b. Excellent power-factor characteristics.

The substitution of two single-phase meters for the polyphase meter is sometimes advocated. This does not change the situation in regard to power factor, but substitutes the adjustment of the two meters for the balance of elements. Where the effect of low power factor or of unbalance of load at somewhat higher power factors causes one meter to run backward, the system will be in error due to the light load adjustment on the reversed meter, which will produce torque in the wrong direction. This may be met by the use of separate meters to record the backward reading, with a ratchet arrangement which allows each meter to record energy delivered in one direction only, as has been done in cases where the direction of the total flow of energy is expected to reverse at intervals. The polyphase meter is usually considered preferable.

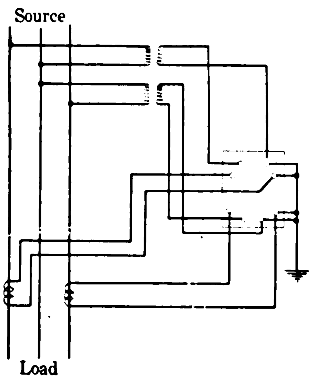

Fig. 1—Connection for Metering on Three-Wire, Three-Phase System with not more than One Point Grounded.

2. Systems having grounds on one side of the metering point. These may be treated as ungrounded systems, using the methods described above, or the system shown in Fig. 2 may be used. Here three potential transformers are connected with primaries in *Y*, the common point grounded, and three current transformers are used with a three-element, polyphase meter, or with three single-phase meters. The three-element, polyphase meter has the advantage of simplicity as compared with the three single-phase meters, but it should be assured that interference between elements is negligible and that a satisfactory balance between elements is assured; once obtained, the balance among elements is quite permanent, while the balance among the three single-phase meters is subject to the usual small variations requiring occasional adjustment.

This method has the advantage of having the power factor of each element of the three-phase meter, or of each single-phase meter, the same as the line power factor on a balanced circuit, approaching the line power factor under unbalanced conditions more closely than the methods previously described.

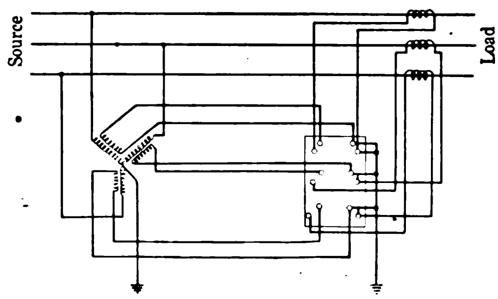

Fig. 2—Connections For Metering on Four-Wire, Three-Phase System or Three-Wire, Three-Phase System with Ground on Both Sides of the Metering Point

To secure good results, it is necessary that the grounding of the primary circuit be sufficient to maintain the neutral at a satisfactory balance at all times among the three phases. If this is not accomplished, the voltages on the individual potential transformers vary with circuit conditions and with the characteristics of the potential transformers themselves, involving certain errors in the potential transformer ratio and phase angle and in the meters.

In some cases this method has been proposed for application to ungrounded circuits, but the uncertainty of the position of the neutral renders it unsatisfactory for the best accuracy. For other reasons it is undesirable also to ground the neutral of the primaries of the potential transformers when the circuit is not otherwise grounded. It is possible to omit the ground on the potential transformer primary and obtain an artificial neutral by balancing the secondary burdens of the potential transformers, but the method requires care in adjustment and therefore, is not to be recommended.

3. Systems having grounds on both sides of the metering point, or a fourth wire. These systems should be treated as four-wire, three-phase systems, using the method shown in Fig. 2. In the unlikely case of an ungrounded, four-wire, three-phase system, the common point of the potential transformer primaries should be connected to the fourth wire.

In some cases, switching operations under different

conditions of load and supply cause important variations in the ground connections. Here the following two fundamental principles govern the method selected:

a. The minimum number of current transformers and corresponding meter elements must be such that under any condition, where a correct record is desired, no more than one possible path for return current past the metering point shall be without a transformer and meter element; in other words, in the circuit of n wires or paths, the minimum number of current transformers and corresponding meter elements required is $(n-1)$.

b. The connection of potential transformers must be such that the unbalance of voltages on their primaries is not in excess of the unbalance of the delta voltages on the primary lines.

In illustration of the first principle, consider a three-phase, three-wire circuit, having a permanent neutral ground on one side of the metering point and an occasional neutral ground on the other; the connection of Fig. 1 cannot be properly used because of possible ground current past the metering point during the presence of the second ground but the connection of Fig. 2 is correct.

An illustration of the second principle: Suppose that, at times, the entire circuit is ungrounded; if the connection of Fig. 2 is used, the voltages on the potential transformers will be subject to unbalance because the relation of the various lines to ground is no longer definitely controlled. Assuming the practise once used in emergency of disconnecting the system ground to continue operation when one line is grounded be followed, two transformers will receive delta voltage and the third transformer no voltage. In this case, the ground must be removed from the potential transformer primary neutral and a voltage balance be obtained by adjusting secondary burdens. These latter practises have been recognized as harmful for other reasons as well, and they are practically obsolete for the type of circuits under consideration. They are mentioned as an illustration of an extreme case only.

Selection of Instrument Transformers

The errors of an instrument transformer appear as an error of ratio and as a phase angle by which the secondary voltage or current departs from its theoretically correct phase for metering. Since the rate of the watt-hour meter and its lag are both adjustable, it is possible to offset known errors, to some extent, by special adjustment of the watthour meter. Since, however, the ratio and phase angle of ordinary instrument transformers vary appreciably with voltage, current, burden, etc., any adjustment of the watthour meter to meet these errors is based upon an estimated average condition and therefore cannot be very accurate. It is, therefore, desirable to select transformers and adjust conditions to give the best possible accuracy without corrective adjustment of the watthour meter. This applies particularly to phase-angle errors of which the variation with power factor makes satisfactory correction impracticable.

Potential Transformers

Standard commercial potential transformers are designed to cover a range of burdens. In the higher voltage sizes, used on most circuits of large power, the accuracy is usually somewhat better than on low-potential transformers. The no-load phase angle is ordinarily negative (secondary voltage reversed leading primary voltage), and several types of transformers are available where this does not exceed 8 minutes at 60 cycles. Non-inductive current drawn from the secondary windings tends to change this angle in the positive direction and lagging current in the negative direction. In the best transformers, it is possible, by increasing the non-inductive current, to reduce the phase angle practically to zero by proper adjustment of

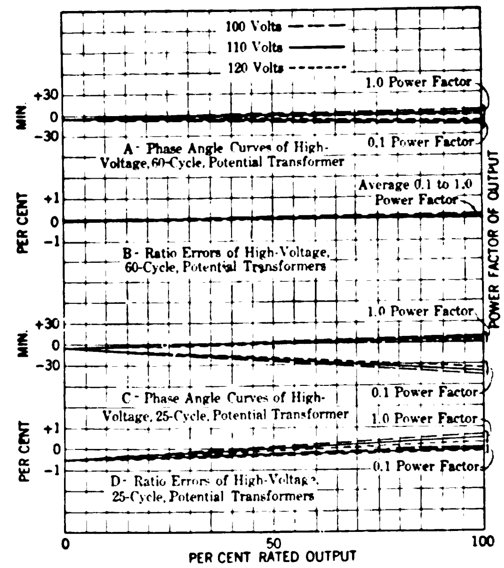

Plate 1—Ratio Error and Phase-Angle Curves of High-Voltage 25- and 60-Cycle Potential

the secondary burden. Even without this adjustment the phase angle with two watthour meters and necessary leads as sole burden may generally be kept within 10 to 12 minutes at 60 cycles.

The no-load ratio is usually low, but this error in many high-voltage transformers is not more than 0.2 per cent at 60 cycles. Either non-inductive or lagging current drawn from the secondary tends to increase ratio, so that frequently the reduction of phase angle by burden adjustment referred to above is accompanied by an increase in accuracy of ratio. The variation in errors of a potential transformer for changes of voltage within the limits caused by ordinary regulation is very small. Whatever ratio error remains may, therefore, be fairly considered a constant error subject to correction by compensation in the watthour meter or by the application of a correction to the final result.

Plate 1, a and b, show average ratio errors and phase

angles of a number of transformers from 22,000 to 66,000 volts at 60 cycles, and c and d show test results on a single 33,000-volt transformer at 25 cycles.

Current Transformers

Standard current transformers are designed to cover a range of burdens. The ratio errors and the phase angle between primary and (reversed) secondary currents vary appreciably with current, secondary burden and large changes of frequency. The phase angles are usually positive, and are increased by increase in non-inductive burden. It is desirable, therefore, to keep both burden and its power factor as low as possible. This means low resistance leads and only the necessary one or two watthour-meters for the best results. The variation of ratio and phase angle with current must also be considered. It is desirable to obtain transformers having as little variation of these errors with current as possible.

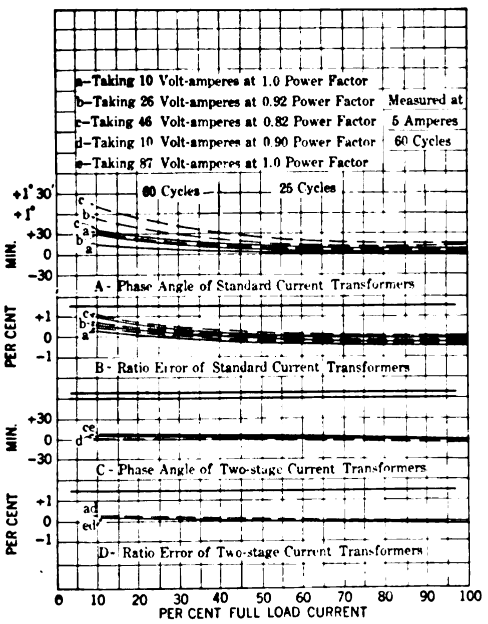

Plate 2—Ratio Error and Phase-Angle Curves of Standard and Two-Stage Current Transformers at 35 and 60 Cycles, with Stated Burdens

On account of the range for which the transformer is designed, the ratio is usually low at low burdens to prevent it from being too high for reasonable accuracy at high burdens. The amount by which the ratio is low on the lowest practicable burdens varies with the practise of the various manufacturers, but does not usually exceed 0.8 per cent maximum. No attempt should be made to bring a low ratio up by additional burdens, as it requires very careful adjustment of the amount and power factor of the burden to produce satisfactory results on ratio and phase angle at a single value of current, while the resulting phase angle (and sometimes ratio) at other values of current becomes rapidly worse. This difference between treatment of potential and current transformers should be noted as resulting from the fact that the potential transformer must be accurate at a roughly constant voltage and current, while the current transformer must be accurate at widely varying currents and voltages. The same results may be obtained by adjustment of the watthour-meter as by a change in the ratio of the current transformer.

Improvement of current-transformer accuracy by special means has been proposed in several forms. A method recently brought out, for which apparatus is beginning to be available, is the two-stage transformer with special watthour-meter. ("The Two-stage Current Transformer," Brooks and Holtz, A. I. E. E. Journal, June 1922.) The two-stage transformer is, in principle, a combination of two transformers in one, in which the second transformer corrects the errors of the first by the use of a simple corrective winding in the watthour-meter. By this arrangement the errors of ratio and phase angle due to the current transformer are greatly decreased as compared with standard current transformers. Typical curves show ratio error held within 0.2 per cent and phase angle within about 6 minutes for a test from 10 per cent to 100 per cent current at 60 cycles with a burden of two watthour-meters in the corrected circuit.

In Plate 2, A and B show average ratio errors and phase angle at 25 and 60 cycles of standard current transformers, and C and D show test results on a two-stage transformer designed for a working pressure of 32,000 volts.

Secondary Connections of Instrument Transformers

To assure the best results, it is preferable that separate leads be used for all secondary circuits, and that the length of leads be kept as short as possible. All secondary circuits of current and potential transformers should be connected to a common ground.

Watthour Meter

The watthours per disk revolution of a watthour-meter will depart somewhat from the nominal value for load current values other than those for which it has been adjusted. On this variation are superposed whatever errors result from changes of temperature, power factor, frequency, voltage and wave form. Certain work now in progress (such as that of Kinnard and Faus, already cited) makes it seem probable that meters of substantially improved accuracy, particularly with regard to errors with varying temperature, are to be available. Temperature compensation is more readily obtained for meter elements operating at unity power factor; inasmuch as one of the two elements of the ordinary polyphase meter usually operates at low power factor, it is greatly to be desired that such studies be prosecuted with a view to obtaining temperature compensation for all conditions of phase departure within the meter elements.

The power-factor error is partly compensated by lag adjustment. The frequency and voltage errors are negligible for the variations occurring in the usual circuits under operating conditions. If special wave-form conditions, serious enough to cause error, exist, the greater part of the error may be eliminated by calibrating the watthour-meter in place by the use of indicating instruments the wave-form error of which is negligible.

The watthour-meter in general service is one of the most reliable devices in measurement work. In view, however, of the large value of the energy measured at the points here under consideration there are cases where it may be advantageous to use two watthour-meters similarly connected to assure a proper record in case of the accidental failure of one meter. In such cases it is proper to designate one meter as the regular standard, and to substitute the reading of the second meter only when reasonable proof of the failure of the first meter to record correctly has been obtained.

Owing to the recent rapid improvement in the watt-hour-meter, detailed data on performance is omitted.

High Frequency Measurements

The second of the studies undertaken in 1924 was in the field of measurement of high-frequency quantities; progress is being made in this investigation but the subcommittee (C. M. Jansky, Chairman, E. D. Doyle, B. W. St. Clair) makes no report at this time.

Dielectric Losses and Power Factor

The matter of measurements in connection with dielectrics, especially solid dielectrics, was surveyed by the committee and a subcommittee appointed as follows: W. A. Del Mar, Chairman, O. J. Bliss, and W. N. Goodwin, Jr. This committee arranged a symposium of papers presented at the First District Regional Convention at Niagara Falls May 26, 27, 28, 1926. The papers submitted are as follows:

The Power Factor of Dielectrics and Insulation, by J. B. Whitehead, Johns Hopkins University

The Mechanism of Breakdown of Dielectrics, by P. L. Hoover, Harvard University

Standards for Measuring Power Factor of Dielectrics, by H. L. Curtis, Electrical Testing Laboratories

The Significance of Errors in Dielectric-Loss Measurements, by C. F. Hanson, Habirshaw Electric Cable Co.

Use of Dynamometer Wattmeter for Measuring Dielectric Power Loss, by E. S. Lee, General Electric Co.

Commercial Dielectric-Loss Measurements, by R. E. Marbury, Westinghouse Elec. & Mfg. Co.

Three Methods of Measuring Dielectric Power Loss and Power Factor, by E. D. Doyle and E. H. Salter, Electrical Testing Laboratories

Compensation for Errors of the Quadrant Electrometer, by D. M. Simons, Standard Underground Cable Co.

The Dielectric-Loss-Measurement Problem, by B. W. St. Clair, General Electric Co.

Zero Method of Measuring Power with a Quadrant Electrometer, by W. B. Kouwenhoven and P. L. Betz, Johns Hopkins University

It is believed that these papers in the total give a reliable index of the present state of the art of measurements involving the higher voltages and small phase angles.

TIDE-POWER DREAMS ARE COMING TRUE

The flow of tides may yet generate a large amount of electric power. This type of project, for years held to be fanciful, is about to get a real start on the international boundary between Maine and New Brunswick. The Federal Power Commission recently granted Dexter P. Cooper a preliminary permit covering a proposed huge development of tidal power in Passamaquoddy and Cobscook Bays, Washington County, Maine. The next step is to secure the same sort of permit from the Canadian government.

On May 27 the private bills committee of the Canadian House of Commons approved the bill to permit Mr. Cooper's plan to be carried out, but added a number of amendments as the bill went to the House for action. One of these provides the Dominion authorities must be satisfied with the allocation of power as between the United States and Canada before the project begins to operate. Other amendments require that a majority of the directors be British subjects and that not more than ten million dollars of bonds be issued.

Mr. Cooper purposes to build a series of dams between various islands and the Canadian and American mainlands so as to trap vast volumes of water in two great pools at a coastal point where the ebb and flow of the Atlantic Ocean tides are strong. Water is to be admitted through 43 gates during the hours that the tide is rising and to be discharged steadily through one or more great electrical generating stations.

The calculations are to obtain a mean operating head of 13 ft. between the two pools created by natural barriers and the dams. A flow of 300,000 second-feet will be counted upon to develop two and a half million kilowatt-hours of electric energy annually through the operation of generators of 600,000 horsepower capacity. There are few electric generating stations in the world with so large a capacity for producing current for electric light and power. The principal market for this power will be down the Maine and Massachusetts coasts to Boston.

Stability Characteristics of Alternators

BY O. E. SHIRLEY[1]

Associate, A. I. E. E.

Synopsis.—*During the past few years, stability characteristics of systems using long lines have been discussed at considerable length, but not so much attention has been given to the characteristics of the load. This paper shows that power limits may be reached with very short lines and certain classes of load.*

The characteristics of several classes of load, such as motors of various kinds with constant shaft output, variable impedance loads (synchronous converters for railways), constant impedance, and miscellaneous combinations, are discussed as they affect the stability of the generator. The criterions for the stability of an alternator as developed by this paper are "short-circuit ratio," saturation, power factor of the load, and character of the load.

A series of curves and a formula for the minimum allowable value of short-circuit ratio as a function of saturation and power factor are proposed for general purpose alternators which may be called upon to deliver power to any of the various classes of load. These curves are derived from characteristic curves of typical machines.

It is not intended that these curves shall be used for generators which supply power over long transmission lines, as the characteristics of these lines may require considerably higher values of short-circuit ratio, and the generator must be specially designed to meet the individual requirements.

* * * * *

For the past few years, the problem of power limits and stability of alternators has been given considerable attention especially from the standpoint of transmission over lines of lengths approaching the maximum economical distances. The effect of exciter stability, the possibilities of automatic voltage regulators, and compensation for armature reaction by compounding through rectifiers have all been quite fully presented. That there are practical limits for stability in operation for certain classes of load, even with short lines, has been suggested in some papers and discussions, but usually as incidental only to the presentation of other features which were covered much more completely.

The purpose of this paper is to discuss the characteristics of the various classes of load, and to propose a set of curves based on the inherent characteristics of a-c. generators to secure a practical degree of stability with the kinds of load for which this factor must be considered, to secure successful operation. These curves are intended for machines operating under ordinary conditions with comparatively low line drop, and will not be applicable for those operating with very long, high-voltage transmission lines.

In recent years the tendency in the design of alternators has been to decrease the short-circuit ratio, that is, the ratio of field current for normal voltage on open circuit to the field current for rated stator current on short circuit. In many cases this short-circuit ratio may go to extremely low values without serious consequences, aside from poor regulation, but with some kinds of load, an alternator with a short circuit ratio very much below unity may not carry swings appreciably above full load and the voltage will "fade" so that part of the load will be dropped. Such a disturbance may be very puzzling to the operator, as the generator will dip in voltage, dropping a considerable part of the load which caused the instability (due to operation of low-voltage relays), and the voltage will then recover to approximately normal. The machine may then operate as though nothing had happened, unless the maximum load for stability is again exceeded. The fading of voltage, or instability, results from a combination of characteristics of machine, line and load. The principal factors determining stability of the alternator are degree of saturation, power factor of load, and short-circuit ratio. For any particular class and power factor of load, and for alternators with the same degree of saturation, there will be a minimum value of short-circuit ratio which is the lower limit for design of these machines if they are to carry full load with the necessary margin in stability. This margin in stability is necessary to enable the machines to carry the ordinary swings in load successfully.

The degree of saturation in the alternator may be represented by the "saturation factor" as defined in the A. I. E. E. Standards.

Curves showing the proposed minimum values of short-circuit ratio for various lagging power factors and saturation factors are derived in this paper by combining load and generator characteristics.

Load Characteristics

1. *Constant Power Output.*

a. Induction motors with practically constant shaft output, such as those driving fans, pumps, compressors, direct-current generators, etc.

b. Synchronous motors for same classes of service as "a."

2. *Variable Impedance.*

a. Synchronous converters supplying power to series motors for railway service.

3. *Constant Impedance.*

a. Light and heating.

b. Electric furnaces, welders, etc.

c. Synchronous converters for lighting load.

4. *Miscellaneous.*

Combination of constant power, variable impedance, and constant impedance loads.

1. Designing Engineer, General Electric Co., Schenectady, N. Y.

To be presented at the Pacific Coast Convention of the A. I. E. E., Salt Lake City, Utah, Sept. 6-9, 1926.

Constant Power Output. Figs. 1A and 1B represent diagrammatically alternators furnishing power to a synchronous motor load and an induction motor load, respectively.

The curves in Fig. 2 show the variation in power factor with voltage for synchronous and induction motors having constant shaft output. The synchronous motor curves are based on adjusting the motor field currents for rated power factors at normal voltage and holding these motor field currents constant for other voltages. The induction motor curve is based on operation at 90 per cent power factor at normal voltage and load. Curves showing variation of current with voltage corresponding to these power factor curves are given in Fig. 3.

The alternator characteristics are represented by the

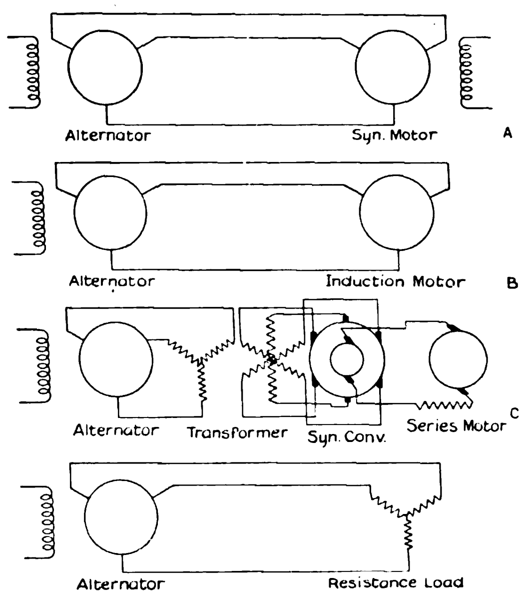

Fig. 1—Diagrams for Various Classes of Load

usual open circuit saturation and synchronous impedance curves. It is possible to design machines with a very wide range of characteristics, but, for the purpose of illustrating the combination of machine and load characteristics, curves for a general purpose alternator with fairly high saturation have been selected.

The values of alternator excitation required with constant power output for a number of voltages, above and below normal, were calculated for the different classes of motors represented in Fig. 2, for the stator currents Fig. 3.[2] Refer to Fig. 5 for these curves. They show that excitation decreases slowly with the voltage to a minimum point and then increases again. The minimum excitation and the corresponding voltage determine the limit of steady-state, stable operation. Refer to Fig. 5, Curve *B*. If the generator excitation corresponds to 92 per cent voltage, and the voltage starts to decrease, due to addition of a very small increment of load, the excitation required at a slightly lower voltage will be less than that actually on the machine, and the voltage therefore will be stable. However, if the excitation is decreased to that required for 88

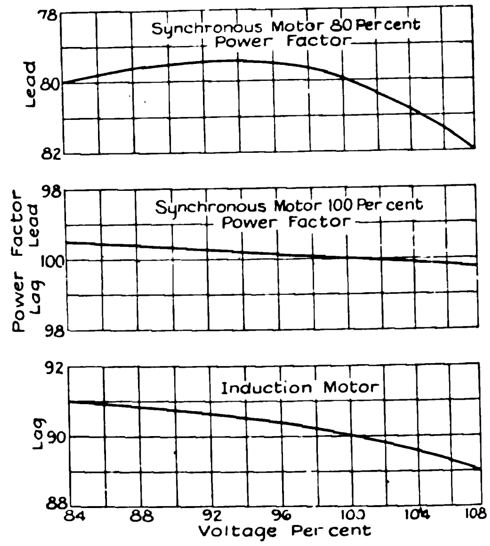

Fig. 2—Variation of Power Factor with Voltage. Constant Power Output

per cent voltage, and the small increment of load is added, the voltage will start to decrease and it will then pass through no value for which the excitation is

C. Induction motor—90 per cent. power-factor lag at normal voltage

sufficient. The voltage will continue to drop until the generator and motors pull out of step.

The curves in Fig. 5 show quite clearly the behavior of an alternator with motor load having constant shaft output, but the maximum power output of the generator

2. *Reactance*, Appendix C., Doherty and Shirley, A. I. E. E. Transactions, Vol. 37, Part 2, p. 1293.

may be determined more simply by a method which has been used in various forms for several years.[3]

The curve between current and voltage at a given power factor and for a constant excitation current is obtained by calculation or test. These curves, calculated for normal load excitation and at the power factor

for normal voltage of each of the classes of motor load in Fig. 3, are shown in Fig. 6. The kv-a. output curves, derived from these curves, are also given in Fig. 6. The voltages for the maximum kv-a. points in Fig. 6 correspond very closely to the voltages for the minimum excitation points in Fig. 5. The curves do not check exactly, because in Fig. 5 the effect of varying power factor is taken into account, and in Fig. 6, constant power factor is assumed. The difference between the two methods is very small, as will be explained later in connection with Fig. 9.

The behavior of an alternator with increasing load at constant power factor is represented by current-voltage and kv-a-voltage curves at excitations corresponding to 80-, 100-, 120-, and 140-per cent load at normal voltage (See Fig. 7). The kw. load, expressed as a per cent of the kv-a. rating, is also given by the dotted curves for comparison. These curves show that the maximum kv-a. points occur at voltages increasing up to a certain value and then decreas-

ing, so that the load will not be reached under practical operating conditions where the machine will be unstable at normal voltage. The curves also indicate that alternators with high saturation would operate at very high loads without becoming unstable, but practical experience has shown that it is necessary to maintain a considerable margin in voltage above the minimum point, and in kv-a. below the maximum point.

In Fig. 9, curves *A* and *A A* are calculated for normal load excitation at 90 per cent power-factor lag; curves *B* and *B B*, for 91 per cent power factor; and curves *C* and *C C*, for 89 per cent power factor. The dotted curves, *D* and *D D*, take into account the variation of power factor with voltage for the induction motor represented in Fig. 2. These curves show that the maximum kv-a. for operation at variable power factor,

such as that with induction-motor load, is very closely approximated by the curve of kv-a. for normal power factor.

The curves in Fig. 7 show clearly the importance of keeping up the excitation so as to maintain normal voltage with this class of load. This result may be secured with hand regulation by operating with excitation corresponding to normal load and voltage, which will give a voltage above normal when the load is lower than the machine rating. A regulator is very effective in maintaining stability up to the steady state maximum capacity of the alternator at normal voltage, but if the load exceeds this maximum value, the use of any of the

present standard regulators will not maintain stability. If, however, the load conditions are such that the maximum load is exceeded only slightly, stable operation may be obtained by regulating for a voltage a little over normal, provided the machine will not be injured by the higher voltage operation.

The maximum kv-a. values given by the excitation curves do not include any allowance for the effect of the lines and the connecting apparatus, or swings in load, and practical operation will require a margin in the maximum capacity of the alternator to take care of these factors. The required margin is a point that must be determined largely from operating experience.

The more important characteristics of the alternator which affect stability are saturation, relation of no-load field strength to armature reaction, and power factor.

It is proposed that the saturation factor, as defined by the A. I. E. E. Standards and the short-circuit ratio,

be used as the criterion of stability for an alternator at any given power factor. The relation of these two factors for obtaining a consistent margin in stability for synchronous-motor or induction-motor load at different power factors is worked out in a later section of this paper.

The problem of stability with long high-voltage lines

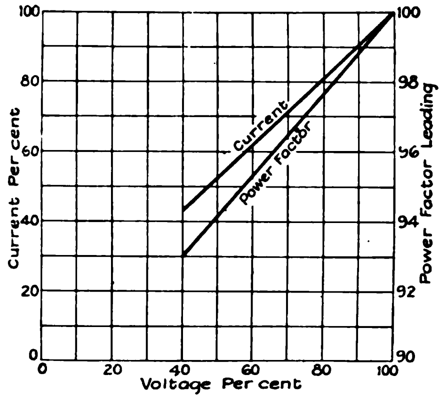

FIG. 10—SYNCHRONOUS CONVERTER CHARACTERISTICS SERIES MOTOR LOAD

D-c. current assumed to vary directly with d-c. voltage.
Curves showing variation of current and power factor on high-voltage side of transformer with voltage on high-voltage side of transformer

and power transmission approaching the maximum line capacity requires a very large increase in stability of the generators and receiving apparatus. A considerable number of papers dealing with this subject have

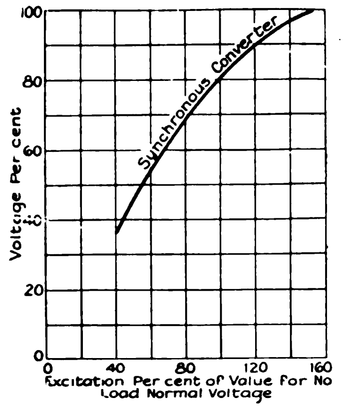

FIG. 11—ALTERNATOR EXCITATION—VOLTAGE CURVES
Synchronous converter with characteristics on Fig. 9

been presented to the Institute, and no attempt is made in this paper to cover this problem.

Variable Impedance Load. A synchronous converter furnishing power to series railway motors is an example of a load with quite different characteristics from the one just discussed. For simplicity in working out the curves, the current on the d-c. side of the converter is assumed to vary directly with the voltage. The power factor on the high-voltage side of the transformer will remain quite close to unity due to the converter being self-excited. The current and power-factor curves are drawn as straight lines, and will approximate the actual conditions quite closely. Fig. 10 shows the assumed curves and Fig. 11 is the corresponding excitation-voltage curve. It will be noted that the excitation continues to decrease with the voltage, instead of having a minimum point as with induction or synchronous motor load.

The stability of the alternator is not a practical factor in a design for this class of load. It is therefore possible to use a machine with a short-circuit ratio of unity to carry very high short-time overloads (one to five minutes) on synchronous converters without trouble from instability, provided the alternator field is increased with load by automatic regulation.

The characteristics of a converter with lighting load are very similar to those just given, and the point of instability is not within the operating range of voltage, but very far below normal. It is possible, by hand or automatic regulation, to maintain normal voltage for

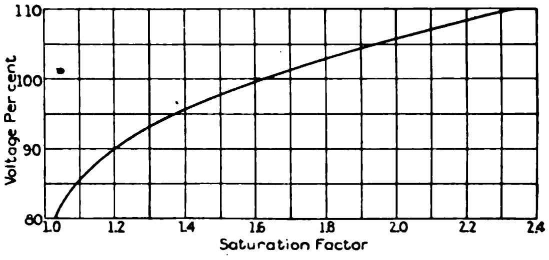

FIG. 12—ALTERNATOR CHARACTERISTICS
Variation of saturation factor with voltage—saturation curve from Fig. 4

any excitation within the heating limits of the rotor winding, and to carry any ordinary swings of load.

Constant Impedance Load. The current in this case will vary directly with the voltage throughout the entire range of load, and the excitation-voltage curve will be almost identical in shape with Fig. 11. With this class of load, the alternator will operate stably at any point on the kv-a-voltage curve, and the load limit will again be determined by the heating characteristics of the machine.

Alternator Characteristics for the Usual Commercial Load. The usual commercial load is a combination of the various classes just discussed and the selection of the generator with the proper characteristics is largely a matter of judgment. The calculation of excitation voltage curves similar to Fig. 5, for various values of load of the same characteristics as the given load, will show whether conditions of instability will be approached sufficiently to be a factor in the design of the generating equipment.

The kv-a-voltage curves, Fig. 7, indicate the maximum capacity for load which is practically all Class 1, but if there is a considerable percentage from Classes 2 and 3, the alternator may operate successfully at voltages below the maximum kv-a. point.

This may be illustrated by an example: Assume operation at 90-per cent voltage, Fig. 7. The maximum kv-a. capacity with Class 1 load under this condition is 104-per cent kv-a. as indicated by the maximum point of curve, *BB*, but, with other classes of load, it would be possible to operate at any point on any of the curves. Combinations of all of these different classes of load will give load characteristics, so that stable operation may be obtained somewhat below the maximum kv-a. point on the kv-a. curves. Just how far below the maximum point stable operation can be secured depends upon the percentages of the different kinds of load.

Derivation of Curves for Short-Circuit Ratio

The saturation factors for several values of voltage, below and above normal, for the saturation curve in Fig. 4 are plotted as a function of voltage in Fig. 12. The kv-a. values for an operating margin of 15 per cent in voltage, as determined by Figs. 7 and 8, are also shown as a function of voltage in Fig. 13.

The short-circuit ratios for various machine ratings corresponding to the kv-a., and voltage values for 90-per cent power factor from Fig. 13, Curve *A*, are derived as shown in Table I, which also includes the saturation factors for corresponding voltages taken from Fig. 12. Similar data were calculated also for the 60-per cent power factor, Curve *B* in Fig. 13. In Fig. 14, Curves *A* and *B* represent, graphically, the relations of short-circuit ratio and "saturation factor" as determined by these calculations.

TABLE I
CALCULATIONS FOR 90-PER CENT POWER FACTOR

Volts per cent	Kv-a. per cent	Current per cent	Open circuit field current per cent from Fig. 4	Short-circuit field current per cent from Fig. 4	Short-circuit ratio	Sat. factor
100	90	90	100	87	1.15	1.65
103	101	98	105	94	1.12	1.84
105	112	107	109	103	1.06	1.94
106	125	118	110	114	1.03	2.04

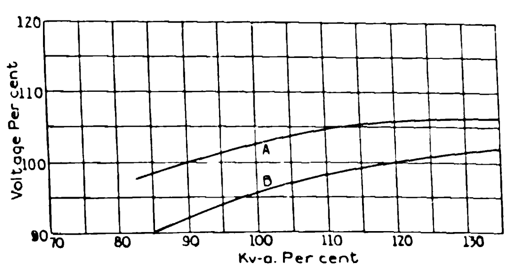

FIG. 13—ALTERNATOR CHARACTERISTICS

Kv-a-voltage curves for 15-per cent margin in voltage—From Figs. 7 and 8

A 90-per cent power-factor lag
B 60-per cent power-factor lag

The determination by trial of a simple formula to approximate these curves in the working range with reasonable accuracy, resulted in the following equation:

$$\text{Minimum } S\,C\,R = 1.4\sqrt{\frac{\text{Power factor}}{100\,F}}$$

Where minimum $S\,C\,R$ = minimum value of short-circuit ratio for rating to give a safe margin in stability for operation at normal rating and F = saturation factor as defined by the A. I. E. E. Standards 7-59: "The saturation factor of a machine is the ratio of a small percentage increase in field excitation to the corresponding percentage increase in voltage thereby produced. Unless otherwise specified, the saturation factor of a machine refers to the no-load excitation required at rated speed and voltage."

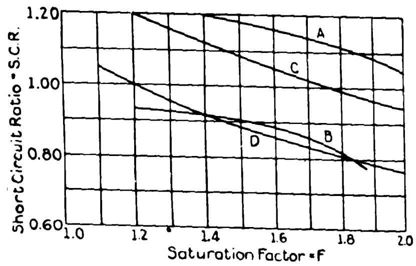

FIG. 14—CURVES FOR RELATION OF SHORT-CIRCUIT RATIO AND SATURATION FACTOR

From Figs. 12 and 13—(See Table I)
A 90-per cent power-factor lag
B 60-per cent power-factor lag

From formula $S\,C\,R = 1.4\sqrt{\frac{\text{Power factor}}{100\,F}}$

C 90-per cent power-factor lag
D 60-per cent power-factor lag

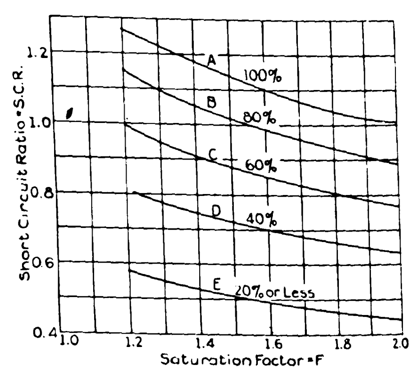

FIG. 15—PROPOSED CURVES FOR MINIMUM VALUE OF SHORT-CIRCUIT RATIO OF ALTERNATORS

A 100 per cent power-factor lag
B 80 per cent power-factor lag
C 60 per cent power-factor lag
D 40 per cent power-factor lag
E 20 per cent power-factor lag

From formula $S\,C\,R = 1.4\sqrt{\frac{\text{Power factor}}{100\,F}}$

The maximum allowable rating for any particular machine is determined by this minimum value of short-circuit ratio.

In Fig. 14, Curves *C* and *D* are derived from tish proposed equation, and a comparison with Curves *A* and *B* shows that for all practical purposes the equation will give the proper values of short-circuit ratio in the usual range of values of saturation factor.

Fig. 15 derived from the equation, covers the entire range of lagging power factors and the usual range of saturation factors. The equation will give results approaching zero as the power factor approaches zero, but since this is obviously impractical, the same values are proposed for power factors of 20 per cent or less. The curve covers lagging power factors only and no attempt is made to work out similar curves for leading power factor, since machines of this class are special and will come within the scope of the design of machines for very long transmission lines.

It will be noted that Fig. 15 gives the proposed minimum value of short-circuit ratio, and it is obvious that any machine with a higher short-circuit ratio will be satisfactory from the standpoint of stability.

Conclusions

Stability of operation of alternator depends on the characteristics of the load as well as on those of the alternator and line.

The minimum allowable value of short-circuit ratio for successful operation is determined by the character of the load, the saturation factor of the alternator, and the power factor. This assumes that the line drop is small enough to be covered by the proposed margin, which will usually be the case with general purpose machines.

When the character of the load is such that the current decreases with voltage, the stability characteristics will not be the determining factor in the selection of the proper value of short-circuit ratio.

The stability characteristics of an alternator for general service, when the load is predominantly motors with practically constant shaft output and line drop is not a serious factor, will be satisfactory with automatic regulation if the short-circuit ratio is not less than that given by Fig. 15.

When the load consists of a few comparatively large motors with swinging load, the proposed curves will give successful operation if the short-circuit ratio at a rating corresponding to the maximum load does not exceed the values indicated by the curves and automatic regulation is used.

Machines designed in accordance with these curves will operate successfully with hand regulation if the increments of load, due to adding more motors, are small enough to prevent excessive drop of voltage before the field rheostats can be adjusted to compensate for the added load.

The proposed values of short-circuit ratio are not applicable to generators for use with very long transmission lines, and the design of these machines is a special problem beyond the field of this paper.

"ELECTRIC LIGHT BED" CURE

Proceeding upon the theory that the dry heat of the sun ever since the creation has been nature's best curative agent and that the light and heat from ordinary electric lamps is the nearest artificial approach to it, Dr. Milton Fairchild of Chevy Chase, just outside of Washington, D. C., has built a long box in which are seven or eight house lamps. It is suspended over his bed by sash cord and window weights and can be drawn down over him leaving only his head protruding after he has turned in for the night. By a rheostat he can adjust the lamps to produce just the right degree of heat. He says it is a great success and that anybody can make one. Already 30 doctors of the Washington district agree with him.

ELECTRIC SHOVEL DIGS BACK TO DEVONIAN AGE

For generations fossil hunting has been a back-breaking process of laboriously picking and shoveling remains of prehistoric fauna out of rock and clay 'way out in a sun-baked desert. Today a huge electric shovel excavated fossilized fishes which lived in the Devonian period. It is doing this in a suburban region that some day will be overgrown by Cleveland and will be rendered forbidden ground for the excavations of paleontologists. The shovel is digging up geologic information by the ton, its electric power having removed all back-break from the process.

Vibration Recorder

For Electrically Measuring and Recording Small Mechanical Movements

BY A. V. MERSHON*

Associate, A. I. E. E.

General Description

THE vibration recorder was first designed to measure vibrations of rotating turbine wheels and the whipping of rotating shafts. The development of this instrument was necessary because ordinary hand micrometers or indicating devices could not be applied to the moving parts due to their inaccessible location.

Most of the parts in a steam turbine are made of iron or steel; therefore, the fundamental thought was to make use of magnetic flux changes to detect these vibrations. A bridge circuit was constructed having a test coil and a transformer coil as one arm, and a dummy coil and a duplicate transformer coil as the other arm. The dummy coil has an iron core with an adjustable air-gap, and the test coil has an iron core the air-gap of which varies with the vibration or motion to be recorded. Any unbalance of the magnetomotive forces produced by the currents in the two transformer windings gives a flux, which produces a voltage on a third winding connected directly to an oscillograph vibrator. An alternating current of approximately 500 cycles is used to excite this circuit.

The voltage of the internal or test coil is balanced against the external or dummy coil to obtain the greatest sensitivity. For convenience in balancing the voltages of these two coils a transformer was constructed with two windings so arranged that the currents in the two windings oppose one another. A third winding was constructed on this transformer to pick up any differences in the voltages of these two coils. The current of the third transformer winding is calibrated to measure the vibrations, in thousandths of an inch, that take place in front of the core of the test coil.

Fig. 1 shows a graphic representation of the currents in the differential three-winding transformer. When the circuit is balanced the primary currents I_2 and I_3 are equal and 180 electrical degrees out of phase. This produces zero flux in the transformer core. If the air-gap in front of one of the coils is changed, it will unbalance the circuits: I_2 will differ from I_3 as shown in the figure and a flux will be set up in the differential transformer core. The flux in the differential transformer core will generate a voltage in the secondary winding No. 1 of the differential transformer, and produce current I_1 in the oscillograph vibrator circuit. The unbalanced currents may not be exactly 180 electrical degrees out of phase with one another, as shown in the figure, as most of the unbalanced condition is due to the change in the inductive reactance of the circuit. This phase variation does not cause errors, as the same variation occurs during calibration.

In each branch of the vibration-recorder circuit there is a variable inductor, a three-dial resistor with steps of 0.1, 1.0 and 10.0 ohms respectively, a coil and a winding of a transformer, all connected in series. The two branches of the electric micrometer circuit are exact duplicates. The connections are shown in the wiring diagram, Fig. 2. Resistances R_1 and R_2 and inductances L_1 and L_2 are secondary parts of the circuit. Their function is to keep the resistance components and the inductive components of the two arms of the electric micrometer exactly equal so that the currents in each half of the circuit will have the same magnitude and the same phase displacement from the impressed e. m. f.

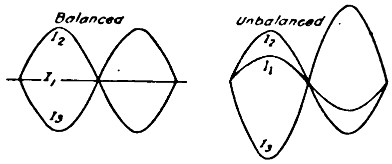

Fig. 1—Graphic Representation of the 500-Cycle Currents in the Differential Three Winding Transformer

Applications. Vibrations as small as five or ten thousandths of an inch have been measured on the periphery of a turbine wheel rotating at 1800 rev. per min. in a steel casing. This was done with the coils exposed to the steam heat and the moisture of the turbine. The whipping of rotating shafts has also been measured. The two above applications were made with an open type coil holder (without a magnetic diaphragm.) Transient oil pressure due to an explosion produced by opening a high-voltage switch in a sealed vessel have been measured with a magnetic diaphragm type of coil holder.

Investigations of the mechanical motions in various kinds of apparatus require changes in the size of the coils and the design of the coil holders. In the majority of investigations coils one inch in diameter by three-quarters of an inch deep have been found satisfactory. The number of turns required varies widely from 500 to 1500. An iron core one-half of an inch in diameter is generally used. The two coil holders in all cases should be built exactly alike so that the dummy coil and the test

*General Electric Co., Schenectady, N. Y.

Presented at the Annual Convention of the A. I. E. E., White Sulphur Springs, W. Va., June 21-25, 1926.

Complete copies containing Bibliography here omitted are available upon application.

coil will have the same magnetic characteristics and the same eddy-current. This will give a rough balance when the air-gaps of the two coils are the same.

A magnetic diaphragm is required in front of the test coil and dummy coil when transient pressures of gases or liquids are being investigated. The diaphragm must be suitably built as a part of the coil holder. In a case where a direct mechanical vibration is produced in a piece of apparatus the coil does not require a diaphragm in front of it. The front of the coil

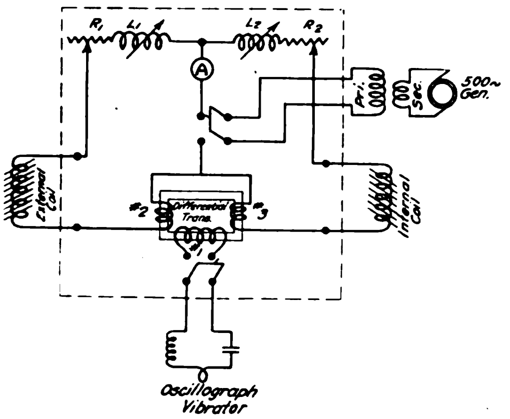

FIG. 2—CONNECTION DIAGRAM FOR THE VIBRATION RECORDER

is placed directly opposite a magnetic piece of material which may or may not be a part of the apparatus being tested. The coil is placed so that there is an air-gap between it and the piece of magnetic material in front of it. Any changes in distance between the magnetic material and the coil can be measured by the change in strength of the magnetic field at various air-gaps.

Sensitivity. Changes in the air gap between the core and the magnetic material of one-thousandth of an inch will produce a deflection on the oscillograph vibrator of from two to five millimeters. The amplitude of the vibration of the apparatus under test is magnified on the oscillograph vibrator 150 times. This magnification ratio is shown in Table I which gives the calibration of the vibration recorder. A magnification of 106 is obtained for small variations in the air-gap, but for larger variations, the magnification is 201.

Accuracy. The vibration recorder will measure accurately any small mechanical movements transient in nature, produced in a piece of apparatus. If this movement is 0.005 in. or greater, an accuracy of five per cent can be obtained.

INSTRUMENT DESCRIPTION AND CONNECTIONS TO AUXILIARY APPARATUS

Fig. 3 shows the vibration recorder as it is developed in instrument form. The two halves of the instrument are practically identical. It is approximately 25 in. long, 18 in. wide and 8 in. high. The ammeter shown in the middle is a standard G. E. type P3. The vibration recorder itself is portable although the oscillograph equipment including the 500-cycle generator is usually not constructed with this point in view.

A one-kw., 500-cycle, 110-volt generator is connected externally through a transformer to the upper left hand terminals marked "500-cycle generator." The oscillograph vibrator circuit is also connected externally to the upper right hand terminals marked "Oscillograph Vibrator." In series with the vibrator in this circuit is an inductance coil and a condenser which is set in dull resonance for 500 cycles. Tuning the oscillograph vibrator circuit accomplishes two results; it reduces the impedance to approximately four ohms effective resistance and likewise keeps down all the harmonics in the 500-cycle wave.

Before the oscillograph vibrator circuit is tuned it is very difficult to produce a balanced condition on account of the harmonics interfering. When it is tuned the harmonics disappear and the circuit can easily be balanced so that the zero line on the oscillograph including all the residual deflection is not more than two millimeters wide. The circuit is balanced roughly by setting the air-gap of the external coil approximately the same as that of the internal coil. A fine balance is obtained by moving the dial resistors and the dial inductors until a satisfactory balance is obtained as indicated on the oscillograph vibrator.

CALIBRATION

The internal or test coil is used to obtain a voltage variation due to the vibration to be measured. The external coil is a dummy coil and its function in the circuit is to furnish a voltage to balance the voltage of the internal coil. The voltage of the external coil is of

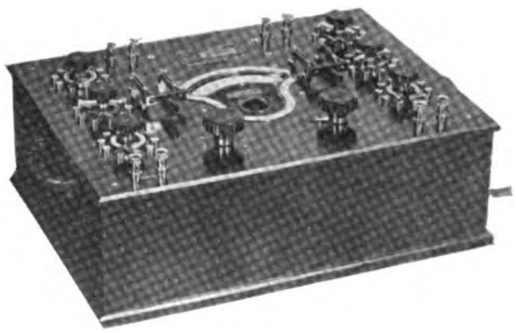

FIG. 3—THE VIBRATION RECORDER
Used to measure transient pressures and mechanical vibrations

a specified value assumed as a zero from which to measure the amplitude of vibration.

When a calibration is started the air-gap in front of the external coil must be set approximately the same as that of the internal coil. The air-gap of the external coil is very seldom changed during the test after the balance is once obtained. The apparatus under test furnishes the internal coil with a varying air-gap corresponding to the vibration that we wish to measure. The variations in the air-gap will be recorded by de-

flections shown on the ground glass of the oscillograph, as illustrated on the calibration curves shown in Figs. 4 and 5. Curves were taken by varying the air-gap of the internal coil while holding constant that of the external coil.

Fig. 4 shows calibration curves for the internal coil for four air-gap settings of the external coil. The air-gap settings should be chosen to correspond with the nature of the test. In order to obtain calibration curve marked "50 mils" the external coil was kept at this

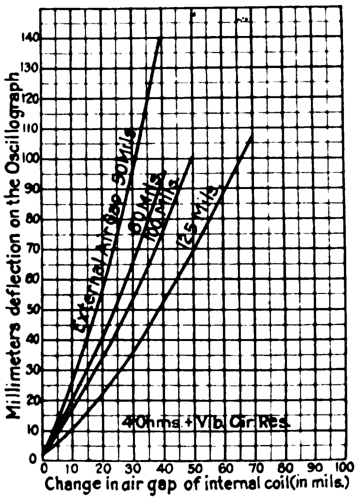

FIG. 4—CALIBRATION CURVES FOR THE VIBRATION-RECORDER CIRCUIT

Showing the effects of various air-gaps between the test coil and the piece of apparatus being investigated

constant air-gap and the air-gap of the internal coil was changed. Readings were taken on the oscillograph of the width in millimeters of the bright band produced by the 500-cycle wave and measurements were taken with a suitable thickness gage, in thousandths of an inch, of the corresponding air-gap in front of the internal coil. In adjusting this air-gap either the internal coil or the piece of apparatus under test may be moved.

The sensitivity of the instrument is best, for changes of five or ten-thousandths of an inch, when the width of the bright band during calibration at the smaller lengths of air-gap of the internal coil is greater than the width of the scale of the oscillograph. The total width that can be measured on the ground glass with the zero in the center of the oscillograph scale is approximately 100 mm. For deflections greater than 100 mm., the oscillograph zero is transferred to one side of the scale and the measurement is made from zero to the maximum deflection. In this case the value obtained by measurement is doubled in order to put the results on the same basis as the smaller deflections obtained with the zero in the center of the scale. The upper points of the curves and the tabulations are made on the basis of the full (or "double") deflection.

Fig. 5 shows the deflection obtained on the oscillograph vibrator using different resistances in series with

0.050 in.	0.000 in.	200. mm.	201.

the vibrator. These curves are shown to bring out the importance of reducing the impedance of the oscillograph vibrator circuit to a minimum by the use of the 500-cycle dull resonant vibrator circuit.

The curve marked "Decreasing Air-gap 4 ohms," was taken by setting the air-gap of both coils at 100-thousandths of an inch and decreasing the air-gap of the internal coil by successive steps. From the increasing curve and the decreasing curve it can be seen that the circuit is unbalanced when the air-gap is changed either way from 100-thousandths of an inch.

Stability of the Circuit

The stability of the electric micrometer is good because the calibration is not affected by slight voltage and frequency fluctuations of the 500-cycle generator. Changes in frequency of $\pm$ 50 cycles will affect the

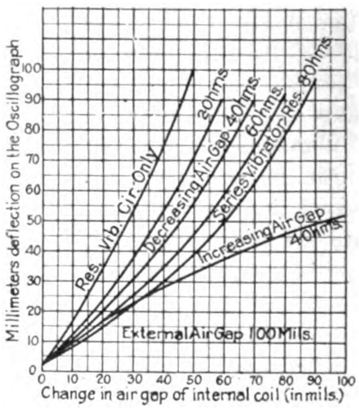

FIG. 5—CALIBRATION CURVES FOR THE VIBRATOR-RECORDER CIRCUIT

Showing the effects of changing the resistance in the oscillograph vibrator circuit

calibration as the iron losses change and the oscillograph vibrator circuit will not be in resonance.

The stability of the circuit is not disturbed seriously due to the internal coil heating up more than the external coil as this uneven heating can be compensated for by changing R_1 and R_2 at any time during the test. Adding 20 ohms to R_1 and 20 ohms to R_2 will not change the original calibration. The best results are obtained if the electric micrometer circuit and the oscillograph galvanometer field are allowed to heat up about one-half of an hour before using.

Tests Results Shown on Oscillograms

Fig. 6 shows a decaying mechanical oscillation of 36 cycles per second which was taken for illustrative purposes only. This oscillation was produced by a vibrating reed clamped to an iron support. Position marked *A* shows the reed pulled over and held 0.044 in. from rest towards the internal or test coil. The reed was first set at 0.125 in. in its rest position. The calibration curve for this film is shown on Fig. 4. Position *B* shows the first cycle after the reed was released and allowed to swing free. The first swing did not return entirely to its original position of 0.044 in. and it, therefore, returned to a position of 0.039 in. representing a total swing of 0.078 in. Position *E* likewise represents a mechanical deflection of 0.036 in. one-half amplitude of the reed. Position *F* represents 0.023 in. one-half amplitude and it is the 12th swing of the reed towards the internal coil which occurred approximately one-third of a second after the reed was released.

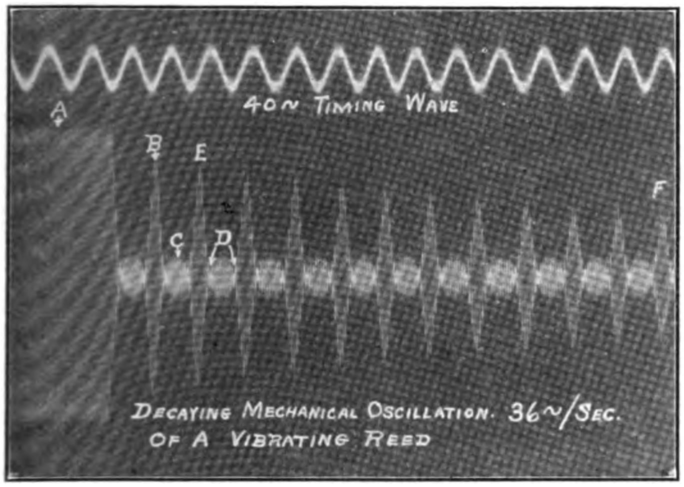

Fig. 6—Oscillogram Showing a Simple Mechanical Oscillation Produced by a Vibrating Reed

Position *B* represents the reed at its nearest position to the internal coil after release and position *C* represents the reed at its greatest distance away from the internal coil in the cycle of which *B* is the beginning. Position *D* represents the reed passing through its rest position or the balanced positions for the electric micrometer circuit. Any simple natural vibrating mass passes through its rest position twice in making a complete cycle.

Fig. 7 is a record of a vibration of an eight-foot diameter turbine wheel rotating 1280 rev. per min. and vibrating 0.024 in. in six segments or nodes around the periphery. The internal or test coil was held in a bracket fastened to a stiff wheel which rotated at the same speed and on the same shaft as the wheel under test. (See Fig. 8) The stiff wheel ran rigidly at all speeds for which wheels are ordinarily tested and had known vibration characteristics at speeds much higher than that of the wheel being tested. Positions marked with an arrow show every revolution of the wheel. In one revolution there are six different positions shown. These correspond to segments between the six nodes or rest positions of the vibrating wheel. Positions 1, 3, and 5 represent negative segments, or wheel displacements from rest, away from the internal coil. Positions 2, 4 and 6 represent positive segments, or vibration from rest, towards the internal coil.

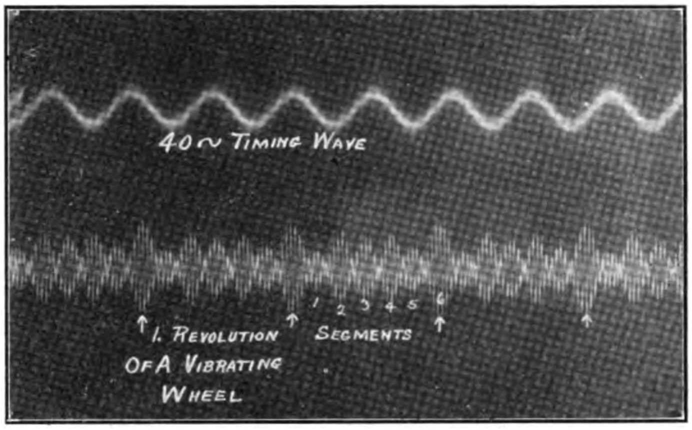

Fig. 7—A Record of a Vibration of an 8-Ft. Diameter Turbine Wheel

Rotating 1280 rev. per min. and vibrating 0.024 in. in six segments around the periphery

The deflections under the arrows are larger than the other five intermediate deflections: The reason for this is that the turbine wheel received a slight end thrust or quiver every revolution. This is likewise shown in producing a smaller deflection next to the largest deflection. This quiver in the wheel for every revolution represents approximately two-thousandths of an inch variation. These total deflections are actual measurements of mechanical movements of 0.012 in.

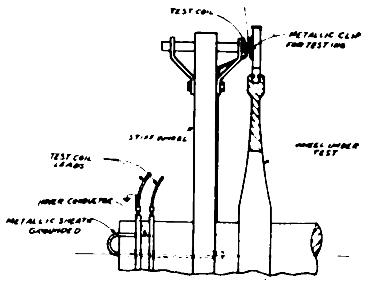

Fig. 8—Arrangement of Test Coil and Holder for Vibration Measurements on a Turbine Wheel

or one-half the total amplitude of the vibration of the wheel. The total amplitude of the vibration of the wheel is 0.024 in. The reason this deflection, shown on the oscillogram Fig. 7, represents one-half the total amplitude of the vibration is that the calibration was taken while the wheel was moved from rest towards the coil. Deflections away from rest do not require a calibration. The mechanical deflections of the wheel on both sides of the rest position are the same.

Abridgment of

The Mechanism of Breakdown of Dielectrics

BY P. L. HOOVER[1]

Associate, A. I. E. E.

Synopsis.—*In attempting to analyze various experimental data that have been obtained in researches on dielectric phenomena in high-voltage cable insulation and other dielectrics, the various existing theories of dielectric behavior have seemed inadequate. A critical study has therefore been made of these theories in an attempt to obtain a working hypothesis that more nearly meets the stringent requirements of experimental facts.*

The logarithmic formula is shown to give erroneous results if applied to high-voltage cables when they are operating under high stress. The gradient in a cable must be calculated from the volt-ampere characteristic of the dielectric when stresses above the elastic limit are used. For stresses below the elastic limit it makes no difference which method is used, but at high stresses an entirely different gradient distribution is obtained when calculated from the volt-ampere characteristic.

Likewise, when an insulation is operated above the elastic limit the stress ceases to be a critical factor, but the strain is of utmost importance. In comparing cables that are operating under high voltages, therefore, the strain at the core should be considered rather than the stress at the core. Stress is given by the voltage gradient and strain by the polarization or the current density in the dielectric.

Since there is always a conduction current flowing, there must be mobile or free ions present. It is assumed that these free ions or electrons come from the molecules of the dielectric and that the number that are present depends on a condition of equilibrium existing between the molecules and the free ions. There exists then a state of kinetic equilibrium between the molecules and the free or mobile ions. Any change in external or internal conditions will disturb the equilibrium and thus change the electrical behavior of the dielectric. Thermal effects and corona effects are accounted for on this basis.

Breakdown occurs when the equilibrium conditions are so disturbed that the insulation as a whole becomes unstable, electrically. High stress or strain and high temperature affect the conditions of equilibrium decidedly.

Corona in gases, oils, and solids consists of minute disruptive discharges that are initiated by rapid changes in equilibrium conditions when the dielectric is overstressed. In solids, however, where the ion mobility is very low and the ion friction high, there will not in general be a corona effect observed because there can be no rapid readjustment of equilibrium conditions. If the insulation is not homogeneous, or if it is composite, there will likely be internal discharges, a corona effect, when the weaker dielectric is overstressed. Moreover, since the molecules of a solid can not readjust themselves quickly to the new conditions of equilibrium imposed by a high voltage suddenly applied, there will be high local stresses and strains set up which may result in mechanical deterioration of the dielectric, that is, chipping or cracking of the dielectric.

Breakdown, therefore, will take place when the insulation is rendered unstable by disturbing the equilibrium conditions, regardless of whether it is due to mechanical strains, electrical strains, or to thermal effects. The tri-fold nature of the phenomenon must be considered in the complete analysis of the problem.

Introduction

The mechanism of breakdown of dielectrics is of the highest importance and yet at the present time it is very little understood. It is the purpose of this paper to discuss and to extend some of the theories of breakdown which have been presented heretofore.

The mechanism of breakdown of single-conductor cables has a particular interest, since the geometry is comparatively simple and it is possible to overstress parts of the insulation without complete rupture taking place. That is, if the gradient is calculated by means of the well-known logarithmic formula for a cable with a ratio of outer to inner radius greater than the Naperian base e and for a voltage near the breakdown value, it is found that the inner layers of insulation are operating at gradients considerably higher than any that the insulation would stand if it were made up in flat sheets. This same effect is brought about whenever a dielectric is in a non-uniform field, although, in general, it is not possible to derive a simple mathematical formula for the gradient distribution of a complex field.

There is, however, considerable justification for skepticism regarding the possibility of overstressed insulation, that is, regarding the validity of the logarithmic formula when used for calculating gradients when the insulation is stressed beyond the elastic limit. In using the logarithmic formula for calculating gradients, it is tacitly assumed that the dielectric has the same electrical constants at and beyond breakdown that it has at low gradients. Reasoning by analogy from other physical phenomena, we should not expect this to be the case; in fact, we would expect new laws to enter as soon as the elastic limit of the material is exceeded. For example, Hooke's law is used in determining the stress distribution in beams and supports of all kinds as long as the elastic limit is not exceeded but beyond the elastic limit Hooke's law does not hold and cannot be used.

Historical Review

To account for these phenomena of overstressed insulation, various theories have been proposed, such as the maximum stress theory, the average stress theory, Fernie's[2] minimum stress theory, Russell's[3] theory, and Osborne's[4] theory. These theories, and in partic-

ular the minimum stress theory, have been discussed at length by Simons[5] and will not be considered in detail in this paper.

Differing substantially from these theories just mentioned is the pyroelectric or thermal theory of breakdown as developed by Wagner[6] and by Hayden and Steinmetz.[7]

The pyroelectric theory assumes that solid insulators have volt-ampere characteristics similar to those shown in Fig. 1, and that this type of characteristic is due solely to the high negative temperature coefficient of resistance of the material.

The question arises, however, as to whether or not this type of volt-ampere characteristic is entirely the result of a high negative temperature coefficient of resistance. Might it not be due, at least in part, to change in resistivity with current density due to some molecular phenomenon? In any case, breakdown will occur when $d E / d I = 0$, for at this point the current will increase to the short-circuit value of the supply.

Günther-Schulze[8] has made a study of the phenomena of dielectric breakdown and states that different definitions of dielectric strength may be given according to the way in which the problem is approached. To quote from his paper:

"Accordingly, the dielectric strength is the lowest potential gradient at which the current through the dielectric is replaced by an independent discharge which is self-increasing. (a spark)." (*Translated*) This gives what Günther-Schulze calls the dielectric impact strength (Stossfestigkeit).

As a second point of view, he gives the following: "These considerations result in the following definition of the dielectric strength: the dielectric strength of a dielectric is the lowest potential gradient at which the bonds between the charges in a dielectric are severed so that a discharge passes through the dielectric." (*Translated*) This he calls the dielectric tensile strength (Reissfestigkeit).

Günther-Schulze then considers various data and concludes or assumes that breakdown in liquids is really a gas discharge in disguise. He states:

"Thus, if an increasing field is applied to the liquid dielectric, the velocity of the ions in the field will increase. But this again means an increased ion friction and an increased heating of those parts of the dielectric that surround the path of the ion. If the increasing field is continued, the heating finally becomes so great that the ions leave an extremely minute, sub-microscopic vapor track in the dielectric. If an ion comes into this vapor track, it is capable of producing new ions through collision, thus initiating the spark discharge, provided the potential drop along the path of the ion is sufficiently high." (*Translated*)

For solid dielectrics he states that the phenomena are somewhat similar. The extremely high ionic friction causes heating effects that result eventually in breakdown. It is, then, the dielectric impact strength that determines the stability of the insulation, the dielectric tensile strength playing a relatively insignificant part in breakdown phenomena.

Thus, dielectric breakdown, according to Günther-Schulze, is a pyroelectric effect. The concept of dielectric impact strength, as he describes it, is only a physical picture, in terms of ions and atoms, of the pyroelectric theory of breakdown.

The concept of dielectric tensile strength, however, should not be thrown aside so hastily. A further consideration of essentially this same idea, but modified considerably and from a different point of view, leads to some very interesting conclusions and results.

Theoretical Considerations

As was first pointed out by Maxwell, the total current in a dielectric consists of the polarization current and the conduction current, the two currents being super-imposed. Is it not possible that there is some relation between them since they are contemporaneous phenomena?

At low gradients there is always a current flowing and this current is due to moving ions or electrons. There is also a certain polarization of the dielectric. At higher gradients the polarization increases and so does the conduction current. That is, the number of mobile charges increases with the degree of polarization of the dielectric. This suggests that the mobile ions must come from the molecules of the dielectric. If this is the case, there must exist a state of equilibrium, a kinetic equilibrium, between the mobile or free ions and the molecules of the dielectric. Increasing voltage gradient would increase the polarization and establish new conditions of equilibrium, the tendency being to increase the number of free ions and thus increase the conductivity of the dielectric. Ultimately a gradient will be reached where the number of ions required to establish the equilibrium will be so great that the molecular bonds will be destroyed and dynamic rupture of the insulation will take place.

The idea of assuming molecular dissociation at comparatively low-voltage gradients may seem rather bold at first sight, but a little thought will show that it does not demand any radical departure from the already well established theories of molecular behavior. In the first place, with liquids, and especially with solids, the inter-molecular fields are quite as important as the intra-molecular fields. The great tensile strength

8. A. Günther-Schulze, The Dielectric Strength of Liquids and Solids, *Jahrbuch der Radioaktivität und Elektronik*, *1922*, Vol. 19, p. 92.

of solids can only be explained on the basis of strong inter-molecular fields. Any change in the molecular structure of a solid produces corresponding changes in all of its physical properties due to the changes in the inter-molecular fields. Consequently it must be assumed that, in solids at least, the electrons in the atom are influenced not only by their own nuclei but also by the fields of the neighboring atoms or molecules. Under such conditions it is probable that the atoms can be ionized; that is, an electron can be removed with much weaker external fields than would be necessary if the atom were isolated in space.

Furthermore, molecular theory demands that the molecules be in motion except at absolute zero, so that any theory dealing with molecular behavior must necessarily be a kinetic theory. With these ideas in mind, it is easy to picture an electron in a dielectric moving about with its nucleus, but also under the influence of the strong inter-molecular fields.

For low gradients, the number of ions drifting, that is the magnitude of the conduction current, will be proportional to the gradient. At higher gradients, as the polarization of the molecules increases, the molecular bonds will become weaker and weaker and the number of electrons which are drifting will increase more rapidly than the gradient increases, and there will be an increase in the conductivity of the dielectric. At some critical gradient the molecular bonds will be entirely broken and dynamic rupture will take place. The phenomenon throughout is essentially that of a kinetic equilibrium between the free or drifting electrons and ions and the polarized molecules of the dielectric.

On the basis of these ideas, the volt-ampere characteristic would have the form of the curves of Fig. 1. Curve A is from some experimental data of Wagner[9] on oiled paper, while Curve B is an empirical curve made to fit Curve A as nearly as possible in order that some numerical computations could be made. The equation of Curve B is

$$e = \frac{175\, i}{1 + 0.1\, i^2} \qquad (1)$$

where e is kv. per cm.
and i is milliamperes per sq. cm.

Referring to Curve B of Fig. 1, it is seen that at low-current densities, *i. e.*, when $0.1\, i^2$ is negligible in comparison to unity, the current is proportional to the voltage. At higher current densities, the current increases faster than the voltage and the curve takes the form shown. The equilibrium conditions are perfectly stable up to the maximum point of the characteristic, at which point rupture occurs. If some means be taken to prevent an excessive current, however, it is possible to maintain stable equilibrium in the dielectric even though it be operated beyond the maximum point of the volt-ampere characteristic. By using a high-resistance, mosaic electrode, Wagner was able to determine experimentally the Curve A of Fig. 1.

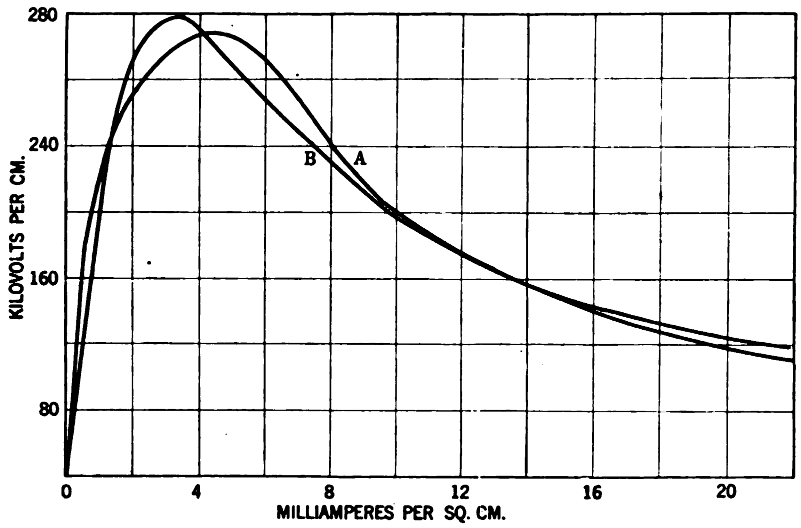

FIG. 1—VOLT-AMPERE CHARACTERISTICS
A. From data of Wagner (Oiled Paper)
B. $e = \frac{175\, i}{1 - 0.1\, i^2}$

CABLE BREAKDOWN

If a cable is constructed of an insulating material having a volt-ampere characteristic similar to those of Fig. 1, it follows that at low current densities the current will be proportional to the voltage. At higher current densities and voltages, when the inner layers begin to be overstressed, the current through these layers will begin to increase more rapidly than the voltage across

9. K. W. Wagner, Loc. Cit. See also Electric Cables, by W. A. Del Mar, p. 79.

these layers. Ultimately, the inner layers will be operating at a point beyond the maximum of the volt-ampere characteristic, but the outer layers, not being overstressed, will prevent complete rupture of the cable.

The possibility of such an analysis by means of the volt-ampere characteristic was recognized and suggested by Peaslee.[10] It is the purpose of the remainder of this paper to carry the analysis still further and to compare the results with certain experimental data.

In the appendix of the complete paper it is shown that the voltage across a cable made from a material with a volt-ampere characteristic given by equation (1), Curve B of Fig. 1, will be

$$E = \frac{175\, I}{4\,\pi} \operatorname{Log}\left(\frac{0.1\, I^2 + 4\,\pi^2 R^2}{0.1\, I^2 + 4\,\pi^2 r^2}\right) \tag{2}$$

Where

E = Total voltage in kv.

I = Milliamperes per cm. length of cable

R = Outer or sheath radius (cm.)

r = Inner or conductor radius (cm.)

$$\operatorname{Log}\left(\frac{0.1\, I^2 + 4\,\pi^2 R^2}{0.1\, I^2 + 4\,\pi^2 r^2}\right)$$

$$= \frac{0.8\,\pi^2 I^2 (R^2 - r^2)}{(0.1\, I^2 + 4\,\pi^2 R^2)\ (0.1\, I^2 + 4\,\pi^2 r^2)} \tag{3}$$

From equations (2) and (3), the puncture voltage of the various cables can be calculated. Fig. 3 shows curves of puncture voltage plotted as a function of the ration r/R and obtained in this way. Curve A is for cables with a constant-conductor radius of 0.158 cm.; Curve B is for cables with a constant sheath radius of 5.03 cm.; and Curve C is for cables with a constant insulation thickness of one cm.

In Fig. 4 are curves plotted from data obtained experimentally by various observers. Curves A and B resemble the A and B curves of Fig. 3. Curves B' and B'' resemble B of Fig. 3, except for the tendency to droop at small values of r/R. The five points in the center of the plot, numbered 1, 2, 3, 4, and 5, are from data by Fernie and correspond to a constant insulation thickness. The points are so erratic in their positions that no representative curve can be drawn.

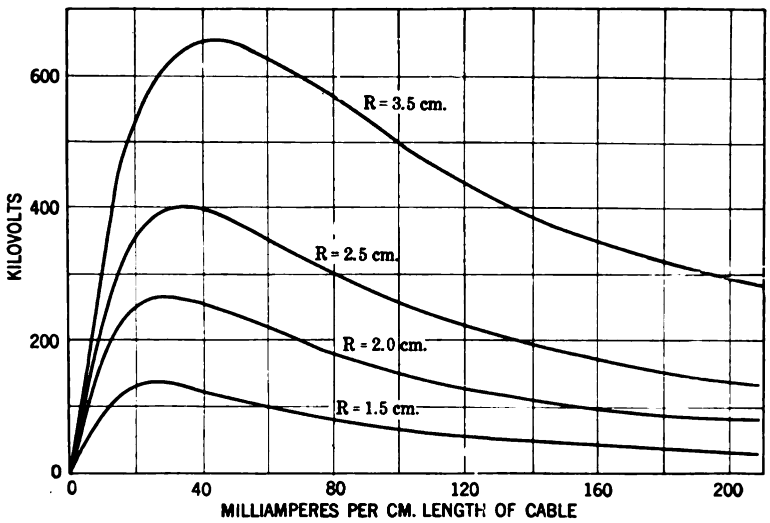

Fig. 2—Volt-Ampere Characteristics for Cables
Inner radius 1 cm.

From equation (2), the volt-ampere characteristics of cables of this material can be plotted. Fig. 2 gives the volt-ampere characteristics for cables of inner radius of one cm. and with various outer radii. These characteristics have the same general shape as those of Fig. 1. This, of course, is to be expected, and it is seen that the cable insulation as a whole increases in conductivity as the current increases. The insulation, however, remains stable regardless of the stress relations in the inner layers until the maximum point of the particular cable characteristic is reached. This point can be found by setting the derivative of equation (2) equal to zero, or,

10. W. D. A. Peaslee, Discussion, Journal of the A. I. E. E., Vol. 41, p. 620, 1922.

They indicate, however, a rough agreement with Curve C of Fig. 3.

These experimental checks are hardly sufficient to establish the theory as developed positively, but the agreement is certainly sufficiently good to warrant further study.

It is of interest to investigate the question of voltage gradient in various parts of the cable insulation on the basis of this theory. The gradient is given by

$$e = \frac{2\,\pi\, 175\, r\, I}{4\,\pi^2 r^2 + 0.1\, I^2} \tag{4}$$

(See appendix of complete paper.)

Fig. 5 gives the gradients in kv. per cm. at various distances from the axis for two cables, when the im-

pressed voltage is equal to the breakdown voltage. It is seen that the maximum gradient is at some point near the center of the wall of insulation and is not at the surface of the conductor, as is ordinarily assumed. In fact, the gradient at the conductor is less than that at any other point in the insulation.

To emphasize this point and to show the change in gradient distribution with increasing voltage, the curves of Fig. 6 are given. It is seen that, for low voltages, the maximum gradient is located at the core and that the gradient practically follows the logarithmic law. At higher voltages, and hence higher current densities, the gradient departs from the logarithmic law and has the form shown by the curves. It is seen that the gradient never exceeds a certain definite maximum. This maximum value is determined by the volt-ampere characteristic, Fig. 1, and for the case illustrated is 178 kv. per cm. The position of this point of maximum gradient moves gradually from the surface of the conductor towards the sheath, but puncture occurs before the sheath is reached.

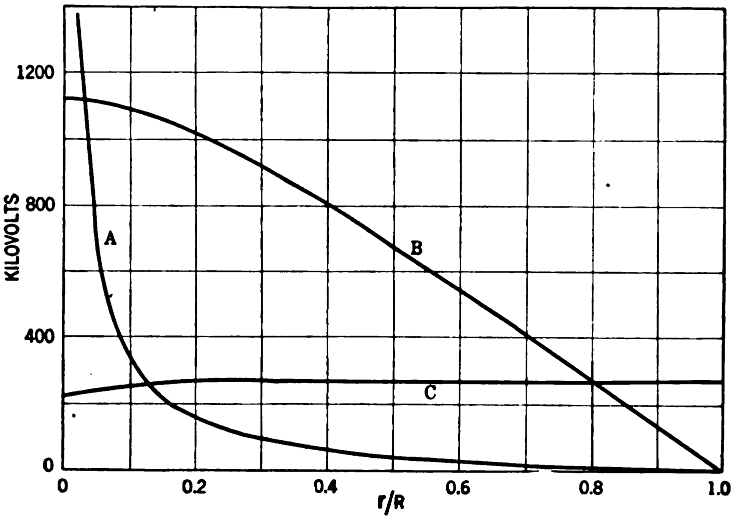

FIG. 3—PUNCTURE VOLTAGE OF SINGLE-CONDUCTOR CABLE VS. r/R

It is important at this time to investigate the stress-strain relations in the dielectric. It seems evident that stress is given by the voltage gradient and strain by the polarization or probably by the current density. We have then the stress proportional to the strain for low stresses, but for higher stresses the strain increases faster than the stress. Finally, the ultimate strength is

exceeded and the strain increases indefinitely even with a decrease in stress. The analogy with the stress-strain relations of mechanics is obvious, the only difference being that the elastic limit and the ultimate strength in dielectrics are probably not as definite as they are in mechanics.

The elastic limit may therefore be defined as in mechanics as that stress at which the stress-strain diagram begins to deviate from a straight line, the ultimate strength likewise being defined as the stress at the maximum point of the stress-strain diagram. The stress-strain diagram of a dielectric is its volt-ampere characteristic.

From the foregoing it appears that in cables operating

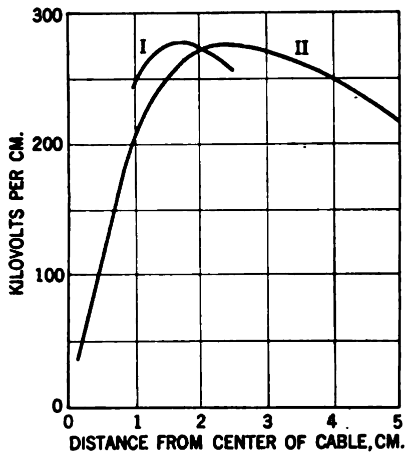

FIG. 5—GRADIENT DISTRIBUTION IN SINGLE-CONDUCTOR CABLES AT THE BREAKDOWN VOLTAGE

I $r = 1.0$ cm.
$R = 2.5$ cm.
II $r = 0.16$ cm.
$R = 5.03$ cm.

at high stresses, the logarithmic formula fails completely to give the correct gradient distribution. Furthermore, it seems that stress or voltage gradient is not the best criterion to use in judging the quality of various insulations when they are operating beyond the elastic limit. Strain is obviously the factor that is of utmost importance when once the elastic limit is passed. Consequently, in comparing various cable insulations, the strain at the core should be used rather than the stress at the core, the strain being given by the current density. This concept is thought to be very important.

There is, however, when alternating currents are used, some question as to whether the total current or simply the in-phase current should be used to determine the strain. The polarization of the dielectric determines the quadrature current and the conductivity and energy loss determine the in-phase current. So long as both of these two components increase uniformly with the stress, the total current will increase uniformly with stress. As soon as one of the components begins to deviate from a linear relation, however, the total current will correspondingly deviate from a linear relation with stress. Furthermore, if a stress is reached where either component of the current increases indefinitely with no further increase of stress, then the total current must likewise increase indefinitely. Consequently it seems immaterial whether the total current or simply the in-phase current is used in determining the strain in the dielectric and it is not evident at this time which of the two will give the best indication of the true strain in the dielectric.

The one outstanding effect that has not been explained is the drooping of the curves B' and B'' in Fig. 4. In these two cases, the sheath radius was kept constant and the conductor was made of smaller and smaller radius. There seems to be a point where further decrease of conductor radius not only fails to increase the puncture voltage but actually diminishes it. It hardly seems possible that an increase in insulation thickness should decrease the breakdown voltage, but such seems to be the case so far as these particular data are concerned.

Osborne's[11] theory explains this effect by assuming ". . . that a solid dielectric, when overstressed, is not disrupted uniformly, but that the material is affected as though it had been pricked by a number of needlepoints."

The ends of these needlepoint ruptures then become points of very high stress and therefore cause rupture of the entire dielectric. Considerable evidence exists supporting the needlepoint theory but little is known as to the origin, nature, and effects of these needlepoint ruptures. Their general character would suggest a high frequency discharge and this suggestion seems to be borne out by further analysis.

Much has been written on corona in oils and in

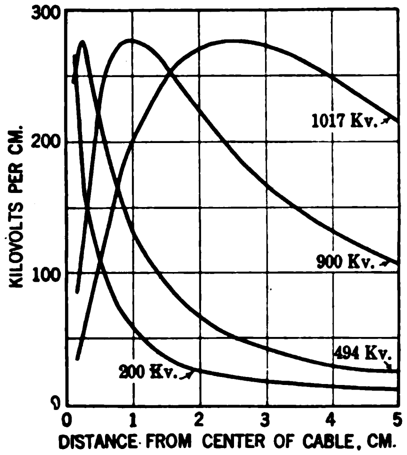

FIG. 6—GRADIENT DISTRIBUTION IN SINGLE-CONDUCTOR CABLE

Breakdown voltage = 1017 kv.
$r = 0.16$ cm. $R = 5.03$ cm.

solids, but there is still cause for considerable speculation as to the fundamental nature of the phenomenon. It probably is a high-frequency rupture. An experimental arrangement designed to show the nature and effects of corona in oils is illustrated in Fig. 7. Voltage was applied between the brass rod and the

11. H. S. Osborne, Loc. Cit., p. 1577.

water sheath. At about 20 kv., numerous discharges took place between the brass rod and the inside of the glass tube A. The apparatus, being transparent, afforded opportunity for visual observations. It was noticed that the discharges resembled ordinary spark discharges except that near the interface between the oil and the glass the spark discharge, or corona, spread out over considerable area; that is, the spark is not strictly radial but seems to consist of streamers that spread throughout an appreciable volume of the oil. Although corona in oil thus consists of disruptive discharges, there is some question as to their needle-like character. In fact, it seems as if these discharges are propagated outward and get thinner and thinner as they go. A somewhat analogous case would be a lightning bolt discharging a cloud by numerous streamers extending throughout the volume of the cloud but uniting to form a single bolt to earth.

The mechanism of these corona discharges in oil is readily understood when we recall the physical picture

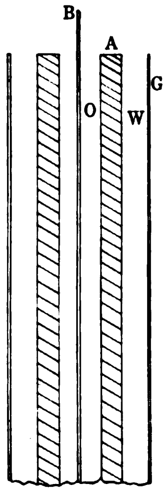

Fig. 7—A, Glass Tube; B, Brass Rod; C, Transformer Oil; W, Water Electrode; G, Glass Tube

of a kinetic equilibrium between the mobile ions and the molecules when the oil is under electric stress. If the oil is under high stress, near or beyond the breakdown point, there will be a comparatively great number of ions free to move, for the molecular bonds will be practically broken. Ions of one polarity will tend to move toward the outer electrode and those of the opposite polarity will move toward the inner electrode. The glass tube prevents any concentration of the ions that are moving toward the outer electrode but from the inner electrode sparks or corona discharges will radiate outward and discharge a finite volume of the ionized dielectric. Heterogeneity of the oil accounts for the concentration of the ion flow and the resulting spark discharge, rather than a more uniform corona glow.

Nevertheless, regardless of the nature of these discharges in the oil, considerable damage is done to the dielectrics. The oil is decomposed, gases being evolved quite rapidly, and the inner surface of the glass tube is badly cracked and chipped. Fig. 8 is an enlarged photograph of a glass tube after a few minutes' application of voltage. The various markings are chips and cracks along the surface of the inner bore of the tube. This tube did not puncture, although some of the cracks extend fully half-way through the wall of the tube.

This chipping and cracking of the glass tube may be due to a rather high temperature locally, or it may be

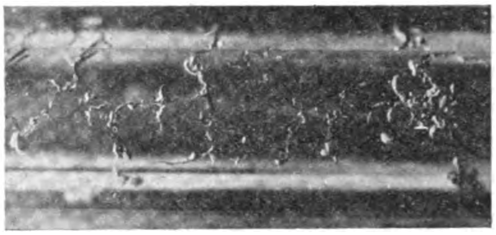

Fig. 8

due to the high-frequency character of the discharges. Peaslee[13] has obtained somewhat similar effects in porcelain. He, however, superimposed high-frequency pulses on the 60-cycle voltage and therefore knew definitely the cause of the phenomena which he observed.

In order to check up on the corona effect in solids, glass thermometer tubes were used. Mercury formed the inner electrode, which was 0.2 mm. in diameter, and water was used for the outer electrode. The ratio of R/r was 33. This tube was known to puncture between 35 and 40 kv., so that 34 kv. was applied and held for half an hour. During this interval nothing happened. There were no visual signs of stress or other effects to indicate that the tube was operating near the breakdown voltage. Due to the large ratio of R to r, the inner layers must have been strained far beyond their breakdown point.

Upon increasing the voltage gradually during 30

Fig. 9

seconds to 37 kv., the tube punctured. Examination showed that there were three distinct places where the tube punctured. Furthermore, throughout the length of the tube the inner wall was chipped and cracked. Figs. 9 and 10 are magnified photographs of parts of the tube. Fig. 9 shows two of the three breakdown points, one at division 26 and one at division 32. The third was at division 50. In Fig. 10 is shown a portion of the tube that was not punctured, but the chips and cracks along the inner bore of the tube are plainly

seen. This effect is undoubtedly a high-frequency phenomenon. There is some question, however, as to whether the high-frequency surges are a consequence of breakdown or are the actual cause of breakdown.

The high-frequency character of the phenomenon is suggested by the fact that several distinct ruptures were observed and also by the numerous chips and cracks along the inner bore of the tube. It is difficult to conceive of this chipping and cracking being due to a simple release of the stress but on the other hand a rapid alternation of stress would very likely result in cracking due to mechanical strains set up as a result of the rapid change in the polarization of the dielectric.

These experiments indicate that corona does not occur in solid dielectrics even when they are operated beyond the elastic limit. Thus the low mobility of the molecules and ions in the solid dielectric tends to prevent the formation of corona and likewise increases the stability of the insulation even when it is operated beyond the elastic limit. This extreme stability probably will not be found, even in solids, if there is any appreciable nonhomogeneity of the dielectric. For this reason composite or laminated insulations are particularly subject to corona phenomena, *i. e.*, internal discharges, when the weaker dielectric is over-strained. The complexities introduced by composite insulation are so numerous that they will not be discussed at this time.

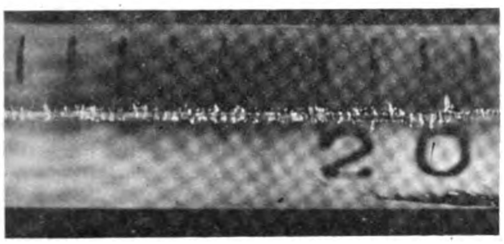

FIG. 10

The drooping of the Curves B' and B'' in Fig. 4 is explained, therefore, by assuming that the inner layer of insulation could not have been homogeneous. In both of these cases very small conductors were used, less than one mm. in diameter. With these very small conductors, it was, no doubt, impossible to get uniform vulcanization of the rubber insulation or uniform solidification of any insulating material. The resulting heterogeneity of the dielectric would cause internal discharge within the inner layers and thus the stability of the dielectric as a whole would be decreased; that is, the puncture voltage would be lower than would be the case if there were no internal discharges.

In this connection, however, it is well to mention some work by Kennelly and Wiseman[15] where they found that for varnished cambric there was a diminution of 14.8 per cent in puncture voltage when an 18.1-sq. cm. electrode was used in place of a 1.13-sq. cm. electrode. However, if sixteen of the smaller electrodes were connected together so as to have the same total area as the larger electrode and if some resistance was inserted between the different small electrodes, the puncture voltage for the combination was the same as for a single small electrode. On the other hand, if the small electrodes were connected by a low resistance as by fastening them into a brass plate, the puncture voltage was practically the same as with a single large electrode. It was suggested at the time that this effect might be due to high-frequency surges, the resistance serving to damp them out and thus give a higher puncture voltage. It would seem that in this case the high-frequency surges took place just before breakdown and were the cause of breakdown taking place at a lower voltage than otherwise would be the case.

CONCLUSIONS

The mechanism of breakdown is not a simple phenomenon. The one fundamental concept is that in the dielectric there is a kinetic equilibrium between the mobile charges and the molecules. However, if there is any appreciable heating effect due to the conduction current or to dielectric losses, the equilibrium conditions will be changed. Therefore, in the complete analysis of the phenomena, the thermal effect must be considered. Then again, if the field is not uniform or if the dielectric is composite or heterogeneous, there is the possibility that part of the insulation will be over-strained and internal discharges are then likely to initiate high-frequency effects that disturb the stability of the dielectric as a whole. All of these three effects are undoubtedly present in every breakdown, but in many cases one or even two of them may be negligible. Experiments can be designed to show any one effect by reducing to a minimum the effects of the other two. It seems that in the past this tri-fold nature of the phenomenon has not been fully appreciated and has been the cause of much confusion. The term tri-fold may be misleading, for they are not three separate effects, but three manifestations of essentially the one phenomenon of kinetic equilibrium between the ions and the molecules of the dielectric.

The author is indebted to the members of the Electrical Engineering staff of the Harvard Engineering School, and especially to Professors H. E. Clifford and A. E. Kennelly, for suggestions in the preparation of this paper. The work has been done at the Harvard Engineering School under the auspices of the Cable Research Committee, which is a sub-committee of the appropriate committees of the National Electric Light Association, the American Institute of Electrical Engineers, and the Association of Edison Illuminating Companies.

Abridgment of

The Rectification of Alternating Currents with Steel Enclosed Mercury Arc Power Rectifiers and their Auxiliary Devices

BY OTHMAR K. MARTI*

Synopsis.—*Recently many publications have been issued on mercury arc rectifier installations in this country and in Europe, as well as on the theory of their voltage and current performances. Nevertheless, it seemed that it might be of interest to give a condensed paper dealing with the most important theoretical treatments, as well as a description of a steel enclosed rectifier of modern design.*

The fundamental theory of these rectifiers is discussed, touching only slightly upon the physical phenomena, but treating particularly of the theory involved in the practical applications. The effects of various factors on the rectifier characteristics and operation are dealt with, and the methods used for calculating the relations of voltages, currents, transformer ratings, etc., are given and tabulated. Moreover, there are mentioned the latest developments of the rectifier proper, as well as the auxiliary devices. Included in this is the design of the transformers from a mechanical point of view, making them rigid enough to stand the mechanical stresses forced upon the windings under abnormal operating conditions; and from an electrical point of view, giving the characteristics of connections such as zig-zag windings, special polyphase windings, and the introduction of reactance absorption coils in the neutral connections of the transformer. Special attention is paid also to the anodes and their cooling equipment, and to the seals, several ingenious points being brought out in their construction.

The vacuum question also is considered one of the most important, not only from the standpoint of producing and maintaining the vacuum, but also from the standpoint of measuring it. The importance of properly measuring the degree of vacuum, as well as the amount of mercury and other vapor present in the cylinder, is brought out, since it was found that the well-known devices for measuring a vacuum, such as McLeod's vacuum gage, did not give the actual conditions existent in the cylinder, but only a relative indication, namely, the pressure of the perfect gases. A new vacuum-measuring gage of novel design, which only very recently has been developed to its present state of perfection, is described in detail and its operation explained. This gage makes it possible to measure and record the absolute pressure of the gases and vapors contained in the rectifier cylinder.

The preparation of the rectifiers for service and their operation are described, and special attention is given to the numerous advantages secured by the use of rectifiers in substations. To simplify operation and to assure continuity of service, a simple and reliable method of ignition and excitation had to be developed. Without touching upon the two methods formerly employed, i. e., d-c.—a-c. ignition and excitation, a new method, lately developed, which proved to be extremely serviceable in practise, is described and illustrated in detail.

The simplicity of starting and operation, the ease of control and the adaptability to full automatic operation, as well as the high efficiencies of these rectifiers, are dealt with and all the advantages are recapitulated at the end. A somewhat exhaustive bibliography, which might be of value to future investigators, is also appended.

* * * * *

Introduction

MUCH information on mercury arc phenomena was published during the period 1892-1911, referring, however, to the mercury arc in glass bulbs only, while the theory of single-phase rectification was especially treated by Steinmetz and Cooper Hewitt. Over 20 years ago, the latter was actually constructing the first rectifier of a practical design which was received with much interest for a time, especially in this country. Steinmetz even gave a theoretical treatment of the two-phase rectifier and discussed the internal phenomena with the help of oscillograms. After a comparatively long period of inactivity, this problem of rectification by means of the mercury arc valve was again taken up, but this time in Europe. The large power rectifier was made possible to a great extent by the construction of an ingenious seal for use with steel tanks. Up to this time only glass vessels could be made sufficiently air-tight.

Inasmuch as in Europe alone several hundred rectifiers are already in successful operation (some of them for nearly 15 years), it may be seen that the steel-enclosed, mercury arc rectifier is equal in its state of development to the rotary converter. Of course, there are still many developments possible, especially in increasing the d-c. voltage. The latest tests in this direction promise results which as yet cannot even be foreseen. The highest d-c. voltage rectifier commercially used,—*i. e.*, 4000 volts,—has been in successful operation for over a year and a half, and tests have been made with as high as 8000 volts. Such high-voltage rectifiers, having an over-all efficiency of over 98 per cent, possess their greatest interest when considered with respect to railway electrification. Later on it will be seen that among the chief advantages of these rectifiers are not only their high efficiency, especially at partial load, but also the decrease in the cost of maintenance and operation.

Although the physical phenomena involved in the operation of the mercury arc rectifier are not fully understood, the quantitative relations upon which rectifier design is based are well established. These relations are given herein particularly with a view to their practical applications, leaving out factors which would only complicate the treatment and do not affect the final results of the computations to any great extent.

The presentation of the theory is based largely on a paper by Daellenbach and Gerecke (see Bibliography).

Presented at the Regional Meeting of District No. 1 of the A. I. E. E., Niagara Falls, N. Y., May 26-28, 1926.

Theory

The underlying principle of operation of the mercury arc rectifier is the valve action of the mercury arc in vacuum, which permits the flow of current in one direction only, from the anode to the mercury cathode.

The fall of potential in the mercury arc is constituted of three parts, a drop of 5.7 volts at the cathode surface, a drop of 6.3 volts at the anode surface, and the drop in the arc proper which is 0.1 to 0.4 volts per centimeter of arc length. Provided the current density in the arc is not too great, the fall of potential in the arc is independent of the current and the voltage of the electrodes and depends only on the nature of the vacuum and on the nature of the electrodes. The voltage drop in a mercury arc is reduced slightly by the presence in close proximity of another arc in which the current is changing. For this reason, in polyphase rectifiers, where this condition exists during the period of overlapping of two consecutive phases, the anodes should be arranged in cyclic order so that the arc passes from anode to anode without skipping.

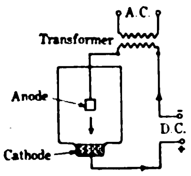

Fig. 1—Single-Anode Rectifier

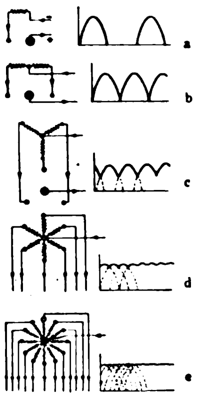

Fig. 2—Single-Phase and Polyphase Rectifiers

When connected to the secondary of a transformer and an external circuit as shown in Fig. 1, current will flow in the direction indicated when the potential of the anode is positive with respect to the cathode. When a single anode is used, Figs. 1 and 2A, current will flow only during one-half of the cycle. By using two anodes with the midpoint of the secondary of the transformer as the negative d-c. pole, Fig. 2B, current will flow over one anode during the first half of the cycle and over the other anode during the second half of the cycle. The full voltage wave is thus utilized and with a sinusoidal pulsating alternating voltage on the a-c. side a continuously flowing pulsating direct current is obtained on the d-c. side. In polyphase rectifiers with more than two anodes, Fig. 2C-E, the current will flow over the anode with the momentarily highest potential and the arc will travel from anode to anode describing a cone with its apex at the cathode.

It is seen from Fig. 2 that the larger the number of phases the better the form of the direct-current wave. However, as will be shown later, the number of phases used is limited by practical considerations. The frequency of pulsation of the direct-current wave is equal to the product of the a-c. frequency and the number of phases. These pulsations can be reduced to a negligible value by means of a choke coil in the cathode circuit.

In considering the current and voltage relations of a rectifier, the following simplifying assumptions will be made: (1) The direct-current wave is assumed to be a straight line. (2) The voltage drop in the arc is assumed to be constant at all loads. (3) The rectifier transformer ratio is assumed to be 1:1. (4) The magnetizing current of the transformer is neglected.

With these assumptions, the current and voltage relations of the rectifier will be derived: First, *neglecting the resistance and reactance of the transformer and line;* Second, *the effect of the reactance of the transformer secondary will be considered.*

Symbols. Following is a list of the symbols used and their explanations:

A Effective value of anode current
E Effective value of phase voltage, primary and secondary
E_d Average value of d-c. voltage
I Constant direct current
I_p Effective value of primary current
L Inductance per phase of transformer secondary
P Average d-c. power
P_1 Rating of transformer primary
P_2 Rating of transformer secondary
$X = 2\pi f L$ Reactance per phase of transformer secondary
$P.F.$ Power factor in line
a_1, a_2, etc. Instantaneous values of anode currents
e_1, e_2, etc. Instantaneous values of phase voltages
e_d Instantaneous value of d-c. voltage
f Frequency of a-c. supply
i_1, i_2, etc. Instantaneous values of transformer primary currents
p Number of secondary phases = number of anodes
t Time
u Angle of overlap
$x = \omega t = 2\pi f t$

1. *Voltage and Current Relations with Zero Transformer Reactance.* We shall consider the general case

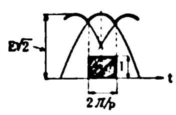

Fig. 3—Anode-Current and D-C. Voltage Waves of a p-Phase Rectifier, Neglecting Transformer Reactance

of a p-phase rectifier, delivering a constant direct current. I. The transformer is assumed to have zero reactance. The anodes then burn in sequence, one at a time, and each anode delivers the current I for an interval of $2\pi/p$. The anode current has the rectangular shape

shown in Fig. 3. Its average value is I/p and its effective value

$$A = \sqrt{\frac{1}{2\pi} \cdot \frac{2\pi}{p} I^2} = I/\sqrt{p} \tag{1}$$

The d-c. voltage, including the drop in the arc and the cathode choke coil, is equal to the voltage between the transformer neutral and the momentarily burning anode. Since the reactance drop is assumed to be zero, the d-c. voltage wave has the form shown in heavy outline in Fig. 3, and its average value

$$E_d = \frac{1}{2\pi/p} \int_{-\pi/p}^{+\pi/p} E\sqrt{2} \cos x \, dx = \frac{E\sqrt{2} \sin \pi/p}{\pi/p} \tag{2}$$

The average d-c. power

$$P = E_d I = E I \sqrt{2} \frac{\sin \pi/p}{\pi/p} \tag{3}$$

The rating of the transformer secondary windings

$$P_2 = p E A = E I \sqrt{p} = \frac{\pi/p \sqrt{p}/\sqrt{2}}{\sin \pi/p} . P \tag{4}$$

For a given transformer connection, the transformer

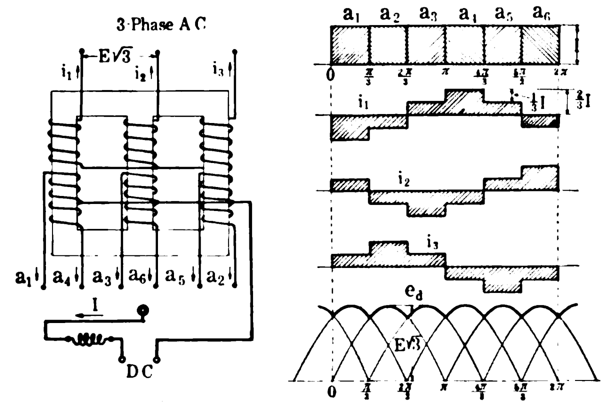

Fig. 4—Anode and Transformer Primary Currents of 3-Y/6-Phase Rectifier, Using the Diametrical Connection of Secondaries

primary and line current waves can be constructed from the anode currents. The effective values of the currents as well as the transformer primary ratings can then be computed.

For illustration we shall compute the voltages, currents, and transformer ratings of a six-phase rectifier with a 3-Y/6-phase transformer using the diametrical connection of secondaries.

Six-Phase Rectifier with Three-Phase, Y-connected Transformer Primary. Fig. 4 shows a 3-Y/6-phase transformer connected to a six-phase rectifier. The numeral subscripts of the anode currents correspond to the order in which the anodes will burn. With the assumption of zero magnetizing m. m. f., the sum of the m. m. f's. around a closed magnetic path in the transformer core is zero. With an assumed 1:1 transformation ratio, we can write:

$$i_1 + a_1 - a_4 + a_6 - a_3 - i_2 = 0 \tag{5}$$

$$i_1 + a_1 - a_4 + a_2 - a_5 - i_3 = 0 \tag{6}$$

Also by Kirchoff's first law

$$i_1 + i_2 + i_3 = 0 \tag{7}$$

Solving the above equations simultaneously for i_1, i_2 and i_3 we obtain

$$i_1 = -\frac{2}{3} a_1 - \frac{1}{3} a_2 + \frac{1}{3} a_3 + \frac{2}{3} a_4 + \frac{1}{3} a_5 - \frac{1}{3} a_6 \tag{8}$$

$$i_2 = \frac{1}{3} a_1 - \frac{1}{3} a_2 - \frac{2}{3} a_3 - \frac{1}{3} a_4 + \frac{1}{3} a_5 + \frac{2}{3} a_6 \tag{9}$$

$$i_3 = \frac{1}{3} a_1 + \frac{2}{3} a_2 + \frac{1}{3} a_3 - \frac{1}{3} a_4 - \frac{2}{3} a_5 - \frac{1}{3} a_6 \tag{10}$$

From these expressions the primary current curves have been constructed in Fig. 4. From equations (**1**) and (**2**) and from the diagram of Fig. 4,

$$A = I/\sqrt{p} = I/\sqrt{6}$$

$$E_d = E\sqrt{2} \frac{\sin \pi/p}{\pi/p} = E\sqrt{2} \frac{\sin \pi/6}{\pi/6} = \frac{3\sqrt{2}}{\pi} E$$

$$I_p = \sqrt{\frac{1}{\pi} \cdot \frac{\pi}{3} \left[\left(\frac{1}{3} I\right)^2 + \left(\frac{2}{3} I\right)^2 + \left(\frac{1}{3} I\right)^2 \right]}$$

$$= \frac{\sqrt{2}}{3} I$$

$$P = E_d I = \frac{3\sqrt{2}}{\pi} E I$$

$$P_2 = p E A = E I \sqrt{6} = \frac{\pi}{\sqrt{3}} P$$

$$P_1 = 3 E I_p = E I \sqrt{2} = \frac{\pi}{3} P$$

$$P.F. = \frac{P}{P_1} = \frac{3}{\pi} = 0.955$$

For other transformer connections the values of currents, voltages and transformer ratings can be computed similarly. These values for various transformer and rectifier connections are given in Fig. 8. Although computed on the assumption of zero transformer reactance and several other simplifying assumptions, *the values of this table are sufficiently accurate for most practical purposes.*

From Fig. 8, it is seen that the primary and secondary of the rectifier transformer have different ratings and that the relation between alternating- and direct-currents and voltages depend on the number of phases and the connections used. *The requirement of transformers of special design is therefore evident.*

Absorption Reactance Coil. The last two columns in

Fig. 8 deal with rectifiers having an absorption reactance coil. The absorption reactance coil, Fig. 5, consists of two windings having a common core. One terminal of each winding is connected to one side of the split transformer neutral. The other terminals are connected together to the negative d-c. pole. The polarity of the windings is such that their m.m.f's. oppose each other.

This arrangement produces a strong choking effect causing both sections of the transformer secondary to deliver currents simultaneously. The effect is that the six-phase rectifier is converted into two parallel working three-phase sections, each section delivering one-half of the direct current.

As a result, the effective values of the transformer currents and the transformer ratings are reduced as seen from Fig. 8, and the regulation of the rectifier is improved as will be shown later.

Effect of Reactance in Transformer Secondary. We shall return to the general case of a p-phase rectifier.

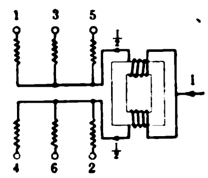

Fig. 5—Absorption Reactance Coil

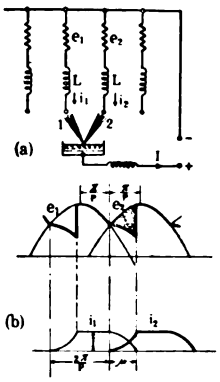

Fig. 6—Anode Current and D-C. Voltage Waves of a p-Phase Rectifier, Considering Reactances of Transformer Secondary

However, each phase of the transformer secondary now has an inductance L. Due to this inductance the anode currents can no longer build up and die down instantly as previously assumed, but the currents of two consecutive phases overlap. Two adjoining anodes, therefore, have their arcs going simultaneously for a short interval, constituting an electrical connection between the open ends of the windings of the overlapping phases. This condition is shown in Fig. 6A.

Anode 1 carries the full current I until the point of intersection of the voltage waves e_1 and e_2, when anode 2 strikes its arc. The instant of this occurrence will be used as the time origin for the expression of the voltages and currents.

Applying Kirchoff's second law to the closed circuit formed by phases 1 and 2, Fig. 6A,

$$e_1 - L\frac{d\,i_1}{d\,t} + L\frac{d\,i_2}{d\,t} - e_2 = 0 \qquad (11)$$

(Since the voltage drops in the two arcs are equal, they cancel each other and therefore do not enter into the above expression.)

Also

$$i_1 + i_2 = I \qquad (12)$$

$$e_1 = E\sqrt{2}\cos(\omega\,t + \pi/p)$$

$$e_2 = E\sqrt{2}\cos(\omega\,t - \pi/p)$$

Substituting for e_1 and e_2 in (11) and solving (11) and (12) simultaneously for i_1 and i_2 we obtain,

$$i_1 = I - \frac{E\sqrt{2}\sin\pi/p}{X}(1-\cos\omega\,t) \qquad (13)$$

$$i_2 = I - i_1 = \frac{E\sqrt{2}\sin\pi/p}{X}(1-\cos\omega\,t) \qquad (14)$$

Where $X = \omega\,L$

The form of the anode current waves during the period of overlapping as determined by expressions (13) and (14) is shown in Fig. 6B. The overlapping of the currents lasts until i_1 has become 0, since the valve action of the arc prevents it from ever having a negative value.

The angle of overlap u can be determined by equating to zero the expression for i_1 with $\omega\,t$ replaced by u.

$$i_1 = I - \frac{E\sqrt{2}\sin\pi/p}{X}(1-\cos u) = 0$$

from which

$$\cos u = 1 - \frac{I\,X}{E\sqrt{2}\sin\pi/p} \qquad (15)$$

From (15),

$$\frac{E\sqrt{2}\sin\pi/p}{X} = \frac{I}{1-\cos u}$$

Substituting in (13) and (14) and replacing $\omega\,t$ by x we obtain

$$i_1 = I\left(1 - \frac{1-\cos x}{1-\cos u}\right) \qquad (16)$$

$$i_2 = I\,\frac{1-\cos x}{1-\cos u} \qquad (17)$$

The effective value of the anode current may be computed by means of the diagram in Fig. 6 and expressions (16) and (17).

$$2\,\pi\,A^2 = \int_0^u i_2^2\,d\,x + I^2\left(\frac{2\,\pi}{p} - u\right) + \int_0^u i_1^2\,d\,x$$

from which

$$A = \frac{I}{\sqrt{p}}\sqrt{1 - p\,\psi(u)} \qquad (18)$$

where

$$\psi(u) = \frac{(2+\cos u)\sin u - (1 + 2\cos u)\,u}{2\,\pi\,(1-\cos u)^2}$$

Compare (18) with (1)

$$P_2 = p\,E\,A = E\,I\sqrt{p}\sqrt{1 - p\,\psi(u)} \qquad (19)$$

The d-c. voltage, *i. e.*, the voltage between the transformer neutral and burning anode, is now reduced by the drop in the inductance of the transformer secondary (see Fig. 6) which is equal to:

$$L \frac{d\, i_2}{d\, t} = \frac{\omega\, L\, I \sin x}{1 - \cos u} = \frac{I\, X \sin x}{1 - \cos u}$$

The average value of this drop

$$d = \frac{1}{2\, \pi / p} \int_0^u \frac{I\, X \sin x}{1 - \cos u}\, d\, x = \frac{I\, X}{2\, \pi / p} \qquad (\mathbf{20})$$

The average d-c. voltage considering the reactance drop is determined from equations (**2**) and (**20**)

$$E_d = \frac{E \sqrt{2} \sin \pi / p}{\pi / p} - \frac{I\, X}{2\, \pi / p} \qquad (\mathbf{21})$$

$$P = E_d\, I = \frac{E\, I \sqrt{2} \sin \pi / p}{\pi / p} - \frac{I^2\, X}{2\, \pi / p} \qquad (\mathbf{22})$$

The transformer primary and line current waves can be constructed from the anode currents as was done previously. For a 3-Y/6-phase transformer the primary current wave can be constructed from the anode currents using equations (**8**), (**9**) and (**10**). The effective value of the primary current and the rating of the transformer primary can be calculated then.

Regulation. Equation (**21**) expresses the d-c. current-voltage characteristic of the rectifier. The first term in the expression represents the d-c. no-load voltage. The second term shows the variation of the voltage drop with load. It is seen that the larger the number of phases the greater is the voltage drop and, therefore, the poorer the regulation. It also explains how the absorption reactance coil improves the regulation. The reactance divides the six-phase transformer into two three-phase transformers having the characteristics of two three-phase transformers in parallel. By converting the six-phase rectifier into two parallel working three-phase sections, the voltage drop is reduced both on account of reduction in the number of phases and the current delivered by each section.

The transformer primary and line reactances have the same effects as the transformer secondary reactance, as far as the d-c. voltage, anode current, and transformer secondary rating are concerned, and could be replaced by an equivalent (not equal) reactance in the transformer secondary. The effect of the primary and line reactances on the transformer-primary current and rating depend on the type of primary connection used and the magnitude of the reactance.

Rectifier Transformers and Their Connections

The transformers used in connection with mercury arc rectifiers are employed not only to step-down the a-c. voltage so that a d-c. voltage of a desired value is obtained at the rectifier terminals, but they serve several other purposes as well, and, therefore, their design and connections differ from standard transformers. The factors involved in the design of rectifier transformers are given below.

The treatment under "Theory" showed that it is essential from certain points of view to have a large number of phases and anodes, respectively (see Fig. 2), in order that the voltage on the d-c. side may be practically constant. Moreover, it could be seen that the rating for which a rectifier transformer must be designed is higher than the d-c. output which is desired from the rectifier. In designing the secondary winding, consideration must be given to the fact that the root-mean-square value of the anode current is considerably higher than the total current divided by the number of anodes. Furthermore, it is essential to keep in mind that in case of a short circuit on the d-c. side, the transformer connected to the rectifier is under more severe stresses than when connected to a rotary converter under similar conditions.

The rating of the transformer for a particular rectifier can be found under "Theory," and also in Fig. 8. Its mechanical construction has to be such that the high electric dynamic forces produced between the anode currents in the windings by a short circuit in the d-c. system are taken care of satisfactorily. Although it is not easy to meet these abnormal conditions, on account of the heavily unbalanced loads which occur, resulting in axial stresses on the coils, these conditions are admirably met in the transformer described below. The coils are always kept under a certain pressure by means of a specially designed support. It is composed of pressure rings of cast steel placed above and below the windings and held together by long bolts and spiral springs, thus forming a solid unit. In order to distribute the axial pressure evenly between the low- and high-voltage windings, an auxiliary ring is placed between the steel-pressure ring and the end-distance pieces of one of the windings, making possible a proper adjustment by means of screws.

The bushings are fastened to a common terminal frame so that the cover of the tank can be removed without taking off the terminals. Reference will also be made to the electrical design of the rectifier transformer in connection with regulation and parallel operation. The voltage regulation depends entirely upon the transformer design, or upon both the transformer and the auxiliary apparatus; since the rectifier itself has no regulating properties, the connections of the windings of rectifier transformers are therefore important. In Fig. 17 A, B, C, D are illustrated various transformer connections; the open terminals of the secondary windings lead to the rectifier anodes.

The term "regulation of the rectifier" refers to the voltage drop between full load and no load at the d-c. side and for several transformer connections usually employed the regulation performance is given below:

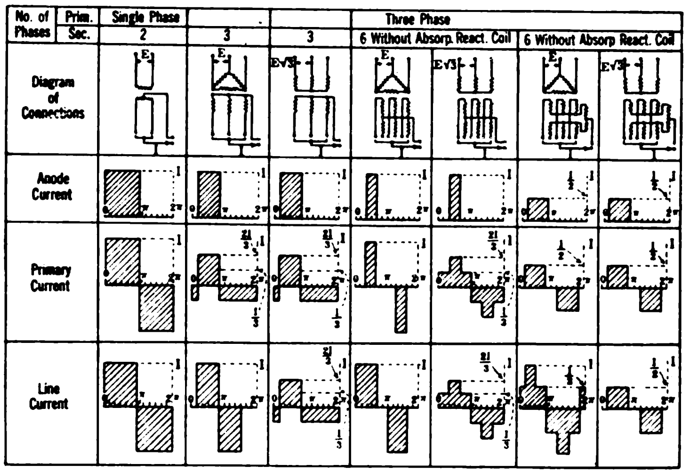
Double six-phase connection, primary three-phase,

Y or delta, usually used with an absorption reactance coil, see Figs. 8 and 17A, has a regulation of about 10 to 12 per cent without and about 4 to 5 per cent with absorption coil;

Polygon connection, primary three-phase-Y regulation about 6 per cent;

Zig-zag connection, primary three-phase-Y, regulation as for polygon connection;

Double zig-zag connection, primary three-phase Y, (used for 12-anode rectifiers or two six-anode rectifiers in parallel) regulation as for the two preceding connections.



No. of phases	Prim.	Single-phase	Three-phase: Delta	Star	Delta	Star	Delta	Star

FIG. 8—VOLTAGE AND CURRENT RELATIONS FOR VARIOUS RECTIFIER CONNECTIONS, NEGLECTING TRANSFORMER REACTANCE AND RESISTANCE DROPS

Construction and Mechanical Details of Power Rectifiers

A cross-section of a Brown Boveri rectifier of recent design is shown in Fig. 10 and described below, although reference will be made to other makes when these differ in some essential point from the above mentioned make.

The large number of different types developed during the years of experimenting have now been condensed into three commercial types. The main differences between these are the difference in the sizes of the various parts, the spacing of the anodes and cathode, and the method of anode cooling. The foundation is very light compared to that required for rotary converters. A special earthquake-resisting foundation has also been developed, which successfully keeps the vacuum piping and other delicate parts intact, even in the countries most frequently subject to seismic disturbances. Six insulating feet, resting on the cast-iron foundation ring, support the rectifier proper. If for any reason it is impossible to lift the rectifier into position, the foundation ring is provided with casters, see Fig. 11, which enable the rectifier to be moved to the desired position. The casters are provided with means for raising the rectifier off the floor while moving it and for lowering it to the floor when it has been put into place.

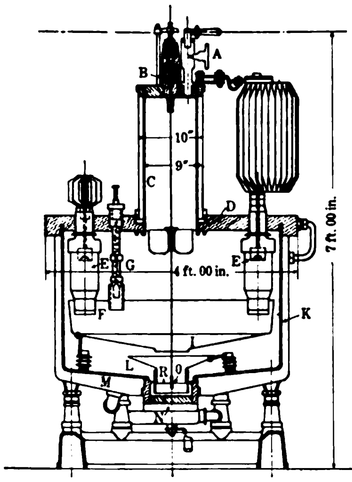

Fig. 10—Cross-Section of a Rectifier

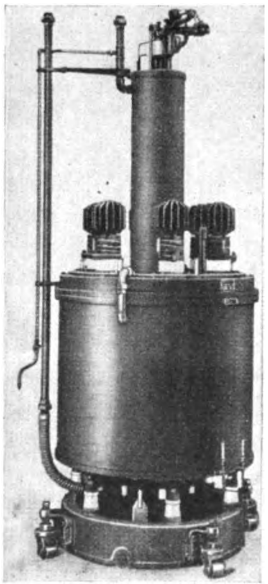

Fig. 11—General View of a Rectifier

Cylinder. In Fig. 10 the cylinder K, made of welded steel, is closed by the anode plate D, which supports the main anodes E, the excitation anodes G, and condensing cylinder C, at the top of which is mounted the ignition device. The cathode consists of a quantity of mercury in the receptacle R. From this the electrons travel through the openings in the funnels L and I, through the so-called arc guide F, to the anode E. The funnels L and I are insulated from each other and from the rest of the rectifier by means of special insulators, visible in the drawing. The arc guide F, shown in detail in Fig. 12, has baffle plates so arranged that no secondary high-vacuum phenomena at the cathode can influence the performance of the anode.

The cooling water enters the rectifier at N, cooling the cathode and the main cylinder, which is specially treated to resist the action of the water for an indefinite period of time. The water then passes upward, through the anode plate D, into the jacket surrounding the condensing cylinder C, whence it is discharged.

The condensing cylinder C serves to cool the mercury vapor so that it becomes liquid and flows down along the walls of the cylinder into a trough, from which it is brought to a point near the wall of the main cylinder K, but outside the aprons L and I, and thence flows back into the cathode receptacle at the bottom of the main cylinder. To the top of the condensing cylinder is attached the ignition plunger, with its solenoid B, which in starting the rectifier acts upon the small iron piece just above it. The pipe to the vacuum pump also leaves the top of the condensing tower, being sealed in the same way as the current conductors.

Anodes. The main anodes are insulated with special porcelain bushings, the shape of which depends upon the voltage for which the rectifier is to be used. The shape of the anodes themselves is shown by the dotted lines. They are made of specially treated steel which has been found, after exhaustive tests, to be best suited to this purpose. The design of the anode cooling system for rectifiers to be used with voltages up to 1600 volts is shown on the right-hand side of the illustration, while the construction of the anodes for voltages as high as 3000 volts is shown on the left-hand side.

The difference in the cooling devices for the two types of rectifiers can easily be understood by taking into consideration the fact that the voltage drop of a rectifier is practically constant for all voltages. It follows, therefore, that while the heat losses in a 200-volt, 200-kw. rectifier are about 20-kw., in a 2000-volt, 200-kw. rectifier they are only about two kw. or about one-tenth of the low-voltage rectifier losses.

The excitation anode with its arc guide is shown on

the left-hand side of the drawing—its function is explained later on.

Like the inner surface of the cylinder K, and all other metal parts inside the cylinder, the anode surfaces are treated in such a way that all occluded air and other gases can easily be removed. This shortens appreciably the time required for forming the rectifiers (about which more is said later on) before they can be put into service. The spacing of the anodes, their shape, and the special manner of treating them, make the rectifier insensible to momentary short circuits, as well as to heavy overloads, which would be disastrous in the case of rotary converters.

Sealing. The seals in the above mentioned make of rectifier are secured by means of mercury, and hence they are not only perfectly air-tight, but they also are not sensitive to the action of the mercury vapor and other gases which are developed in the cylinder. Furthermore, they can be equipped with a visible indicating device.

The Allgemeine Elektrizitats Gesellschaft of Berlin employs a composite packing of aluminum and lead, the former dealing with the high vacuum while the latter forms the seal against the atmosphere. An intermediate space is provided between the aluminum and lead seals which is itself evacuated, and serves to distribute the pressure in such a way that each seal has to deal only with a part of the total pressure difference. For inspection and testing purposes, however, it is necessary to fit each seal with a vacuum pipe, and in case of a leaky cylinder each vacuum pipe of the series must be connected to the gage in turn until the faulty seal has been discovered. Moreover, thorough investigation revealed the fact that mercury vapor and other gases will affect such metal seals to a certain extent, and unless iron is used, an amalgam is formed which may destroy the seals in a very short time. Furthermore, these investigations showed that due to aging of the metals, all inner elasticity is lost after a year or two and that repeated tightening after successive intervals will not remedy the trouble.

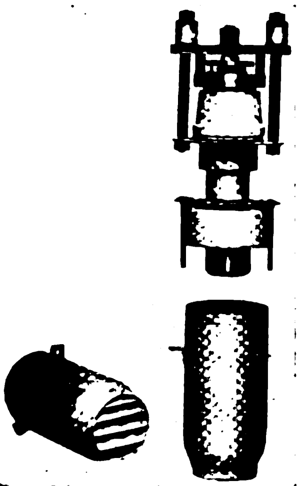

Fig. 12—Anode with Arc Guide

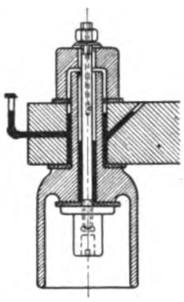

Fig. 13—Mercury Seal with Indicating Gage.

The General Electric Company's glass seal which was recently mentioned in an article on rectifiers may prove to be very effective, and it will be interesting to learn how it stands up in practise. The description of it given in the article did not contain enough information to permit a thorough discussion of it. However, the disadvantage of these seals seems to be that there is no possibility of detecting any leakage, and that when the anodes are removed the seals are destroyed.

The construction of the Brown Boveri seal is shown in detail in Fig. 13. The joints are first fitted with special elastic washers, and thorough investigation, carried on for an extended period, showed that an asbestos washer (double cross-hatched shading) was most suitable. The mercury (solid shading) is then poured into the annular spaces between the anode plate and the insulating bushing, and the insulating bushing and the central conductor, respectively, thus sealing the vacuum, while the asbestos keeps the mercury from flowing into the cylinder.

One of the most important features of the mercury seal is the fact that in case any mercury should filter past the asbestos packing it would only find its way to the mercury cathode at the bottom of the cylinder, doing absolutely no harm. At the same time the leak would be indicated at the mercury gage with which each seal is equipped. The gage, therefore, makes it possible to check instantly the condition of each seal, and if necessary the bolts can be tightened before the vacuum is broken.

Ignition and Excitation. The ignition of the arc is accomplished by means of a small plunger, O, usually located, as in Figs. 10 and 14, within a few millimeters of the surface of the mercury cathode in the receptacle R and connected to a special metal rod extending from the top of the condensing cylinder. This plunger is controlled by the solenoid B, located at the top of the condensing cylinder, which pulls the plunger into the mercury cathode against the action of a spring. As soon as the plunger touches the mercury, the solenoid is de-energized and the plunger is withdrawn. In a fraction of a second an arc is drawn between the mercury cathode and either the excitation or the main anodes, provided the vacuum in the cylinder is sufficiently high and a load is connected to the d-c. circuit.

When working at very light loads the main arc has a tendency to become unstable, and may be extinguished. Therefore, when the d-c. demand is highly fluctuating, as in traction systems, rolling mills, etc., where the current might drop below the value which is necessary to maintain the arc, the cylinders are equipped with excitation anodes. A cross-section through such an anode G is shown in Fig. 10 and it is indicated in Fig. 14, where it is denoted by A_e. The construction of it is similar to that of the main anode, and it is located at about

three-quarters of the total distance between the cathode and the main anode. Much investigation had to be done in order to find the proper location and shape of the excitation anodes so as to prevent condensation of mercury at the main anodes in case the main arc should be extinguished for a considerable length of time. The latest development in this line is the recently developed pure *a-c. ignition device*, by which means the necessity for a special ignition converter is obviated. Trial tests in two Swiss installations demonstrated

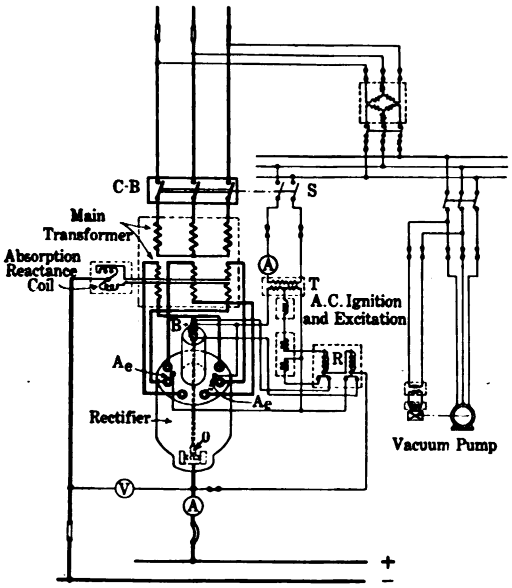

FIG. 14—TYPICAL DIAGRAM OF CONNECTIONS, SHOWING A NOVEL TYPE OF IGNITION AND EXCITATION EQUIPMENT

the superiority of this novel method which is of the utmost importance in connection with fully automatic substations. A full description of a plant equipped with such an ignition and excitation apparatus is given below under "Operation."

AUXILIARY DEVICES

On a rectifier equipment of the simplest form there is only one important auxiliary provided, namely, the vacuum pump and measuring gages illustrated in Fig. 16A. A high vacuum is absolutely essential to the satisfactory operation of the plant.

The pumps used are of special design, and very efficient, so that there is no difficulty in producing a high vacuum in a properly sealed rectifier cylinder. There are several types of vacuum pumps in use, but owing to the scope of the subject, a description of them will not be given here. Just as essential as the pump for producing the vacuum is the device for measuring it. An improvement of the utmost importance has recently been made in this line, which will be described below.

The familiar McLeod mercury column gage used in connection with rectifiers and in laboratory work has been superseded by a direct-reading hot-wire vacuum gage which in size and purpose is similar to the shunt of a precision millivoltmeter.

It may be recalled that McLeod's gage is based upon the fact that the pressure of a perfect gas times its volume is always constant. This law of Boyle's holds true, however, only for perfect gases, and therefore the use of the above gage furnishes no information about the other gases and the vapors of water, mercury, etc., which the cylinder might contain. Another disadvantage of this gage is the fact that it is not direct reading, and cannot be used for automatic station control.

The development of the new direct-reading gage, therefore, made it possible for the first time to study scientifically several phases of the mercury arc rectifier and the influence of the degree of vacuum upon its operating conditions. The latest improvements in the operation of rectifiers are a direct result of the increased ability, made possible by this instrument, to measure high vacuums.

Novel Hot-Wire Vacuum Gage. The arrangement of the direct-reading measuring device as shown in Fig. 16A and B consists of the following important parts: a hot-wire sealed-vacuum gage 1, illustrated by Fig. 16A, a resistance 4, a shunt 5, and a precision moving coil voltmeter 6. The connection to the vacuum piping of the rectifier is shown at *E*.

The working principle of the hot-wire vacuum gage is based upon the fact that the thermal conductivity of gases depends upon the gas pressure. If two bodies at different temperatures are placed opposite to one

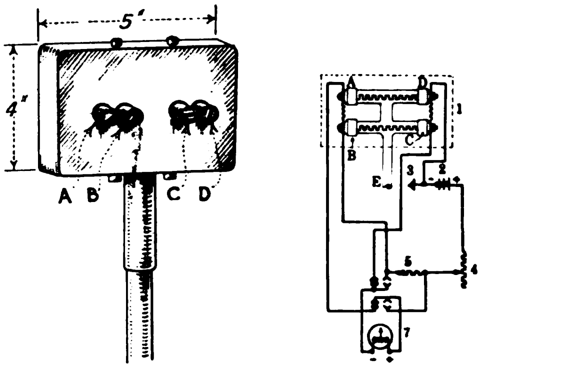

FIG. 16A—NOVEL ELECTRIC HOT-WIRE VACUUM GAGE
B—DIAGRAM OF CONNECTIONS FOR GAGE AND RECORDING INSTRUMENT

another, a heat transfer takes place from the warmer to the colder body, partially by radiation and partially by conduction. It must be kept in mind that (1) the radiation is independent of the gas pressure existing between the two bodies, and that (2) the heat conductivity depends mainly upon the respective pressures. In an absolute vacuum the latter are zero. At first the conductivity rises in proportion to the increasing gas pressure, while the latter approaches asymptotically a constant limit of value. In the range of small pressures,

the thermal conductivity is, therefore, a measure of the gas pressure.

The gage consists of four resistance wires connected together like a Wheatstone bridge. The wires stretched between the terminals *B C* and *A D* are located in the vacuum, while the wires *A B* and *C D* are exposed to the atmosphere, as shown in Fig. 16B. They are electrically heated with a constant current of about 100 milliamperes. When the branches *B C* and *A D* of the bridge are heated, their ohmic resistance and the pressure difference between the points *A* and *C* increase in proportion to the vacuum. Since this potential difference varies with the degree of vacuum, the deflection of the meter varies in proportion, giving a continuous indication of the vacuum in the rectifier cylinder. On account of the special bridge connection, fluctuations of the room temperature have practically no influence on the reading of the vacuum gage. For the safe operation of the voltmeter, the lead from terminal *D* is grounded at 3.

The millivoltmeter is designed as a contact voltmeter with two adjustable contacts which are set for predetermined low and maximum values of the vacuum, and, therefore, can be used for the automatic control of the air-pump set, making possible a full automatic control of a mercury arc rectifier substation.

The hot-wire vacuum gage is connected to the vacuum piping by means of a flange and a high-vacuum stuffing box. When connecting the apparatus, the vacuum gage is first fitted with the stuffing box, after which both parts are connected to the vacuum piping, and finally the stuffing box filled with the sealing mercury. This is essential in order to prevent the outer and inner parts of the vacuum gage from coming into contact with the mercury or the mercury vapor.

The arrangement with the battery 2 furnishing the direct current for the bridge has been superseded by an arrangement allowing the use of alternating current taken from the normal control circuit of the plant. The principle upon which the measuring device is based is the same, but this arrangement does away with the battery and makes the apparatus very simple and consequently fool-proof.

Next in order would be mentioned the ignition converter providing an independent source of current to start the arc. But recently made improvements on the Brown Boveri type rectifier made such a converter unnecessary, and, as can be seen under the next heading, starting is accomplished by means of alternating current furnished from the control circuit.

Cooling. In order to carry off the heat produced by the arc, the rectifier cylinders are usually cooled by means of water, as described above. In case fresh water of sufficient quantity and purity is available near the plant, no auxiliary device is necessary; otherwise, a small pump is required. This pump, usually electrically driven, continuously circulates the water through a recooling system, which consists of radiators mounted near the rectifier installation.

Another auxiliary of importance is the absorption or regulation reactance coil placed in the neutral point of the main transformer, its function being to limit the inherent regulation of the complete plant to a reasonable figure—usually of the order of five per cent from full to approximately no load. Without this coil the regulation may be as high as 10 to 12 per cent unless special transformer connections are used. Further details are given under "Theory" and "Transformers."

Operation of Rectifiers: Single, in Groups, and with Rotary Converters

Before a mercury arc rectifier can be placed in service, a certain "forming" process has to be carried out. The forming itself consists of expelling the gases occluded in the metal parts of the rectifier, chiefly in the anodes. To be able to conduct this process intelligently, it is essential to have a measuring gage which indicates not only the pressure of the perfect gases, but also the pressure of other gases and vapors present. Some of the late t improved methods along this line have to be credited to the hot-wire vacuum gage previously described.

In order to shorten the forming process, it is important that all moisture and humidity be removed from inside the tank beforehand. This is done by the application of high heat, either by passing current through the rectifier, or by circulating hot water. If an electric current is used, it is gradually increased from a low value until the anodes are brought to maximum heat. At the same time the vacuum pump exhausts the gases liberated from the anodes. Various schemes were tried out to faciliate and hasten this preparation for the forming process. This preparation is of the utmost importance in that the gases occluded in the metals can otherwise not be expelled at all, or only very slowly, when the cy inder is being finally evacuated.

Forming is usually started by treating each anode individually, the d-c. energy being dissipated in a small grid resistance. This is followed by six-phase forming, during which t me the rectifier may be connected to a commercial load. The time spent in forming at the factory varies between two and three days, and generally a similar procedure is carried out during erection at the power plant or substation. The forming process should be continued day and night with as few interruptions as possible, and therefore needs careful attention. It is understood that during this process the pumps have to be in operation continually, and also for a further length of time after the rectifier has been placed in service. Both processes have been very carefully worked out in every detail, and their successful application is a direct result of long and elaborate experimenting.

One of the difficulties that had to be overcome in connection with the satisfactory operation of the mer-

cury arc rectifiers, both during forming and in actual service, was internal flashing-over or back-firing. Such internal disturbances, which paralyze the valve effect, were overcome after years of investigation. They have occurred sometimes when the forming process was not carefully carried out, or because of neglect in properly checking the material, especially that used for the anodes. However, if the proper precautions are not taken, such disturbances can occur during the forming process even now.

Ignition and Excitation Control of Novel Design. A typical diagram of connections is given in Fig. 14, which shows all the auxiliary gear of a rectifier controlled and operated in an ingenious way. The outstanding feature is that the controlling, starting, etc., are accomplished by means of alternating current, which is taken from the usual control circuit, fed from the high-voltage line through an auxiliary transformer. No direct current is needed to strike the arc nor to control the ignition anode. The fact that it was possible to dispense with the d-c. source, usually a specially designed converter set, and the development of a simple control arrangement for both ignition and excitation, account for the very simple layout of such a plant, which can be made fully automatic by merely adding two special relays.

The rectifier starts automatically as soon as the circuit-breaker *C B* on the high-voltage side connects the main transformer to the high-voltage line. This breaker is mechanically coupled to the switch *S*, which connects the excitation transformer *T* to the a-c. control circuit. As soon as the switch *S* is closed, the ignition solenoid *B*, see also Fig. 10, is energized, and the ignition anode consisting of plunger *O* is immersed in the mercury cathode, thereby closing another circuit through the right-hand secondary winding of the excitation transformer *T* and the two relay coils *R*. The right-hand relay, as soon as it is energized, in turn opens the ignition coil circuit, and the ignition anode is withdrawn from the mercury cathode by the action of the spring, thus striking an arc and enabling the rectifier to pick up load on the d-c. side at once. Should it happen that the polarity is not correct, the arc is immediately extinguished and the right-hand relay deenergized again, thus causing a repetition of the ignition process until the arc has the correct polarity. As soon as the excitation anodes are working the ignition circuit is broken by the action of the left-hand relay *R*.

The time which elapses from the moment the circuit-breaker relay receives an impulse to close the circuit breaker to the moment the rectifier is able to handle load is usually less than two seconds. The value of such a simple and quick operation cannot be appreciated enough in connection with automatic substations, as well as in other ways. For instance, in substations equipped with rotary converters, it is possible to have a rectifier as a spare set which can instantly be placed into service to take care of peak loads of such short duration that the rotary converters as reserve units would miss them because of the time involved in starting them.

The d-c. voltage is controlled either by step-by-step regulation from the primary side of the transformer or by an induction regulator, hand or automatically operated. The arrangement with the induction regulator is decidedly preferable for lighting supplies, as the voltage can be varied smoothly and to any extent. For the case of traction supplies, and where the question of regulation is not of primary importance, the rectifier can be given a shunt characteristic with a four- or five-per cent rise of pressure with falling load, by the use of specially designed transformers or an *absorption reactance coil* connected in the neutral of the main transformer; see Figs. 5 and 14. Reference to the latter arrangement has already been made under "Theory" and further details of these two methods will be given below.

Parallel Operation. It is possible to feed two rectifier cylinders from one main transformer and in such a case it is essential that each cylinder takes its proper share of the total load. Moreover, a number of rectifiers, all fed from the same primary supply, must be able to operate in parallel with each other. Furthermore, a rectifier might be added to an existing d-c. plant, and have to operate in parallel with existing rotary converter or mercury arc rectifier units. In all these cases certain conditions must be fulfilled in order that the units may supply power to the same bus-bars without interfering with each other, and that each may take a proportionate share of the total load. In considering the conditions necessary for satisfactory parallel operation of rectifiers, it has to be kept in mind that the rectifier cannot feed back to the a-c. line, and also that the inherent load characteristics of rectifiers are somewhat different from those of other converters. Some of the essential considerations relative to these facts are given below.

For all practical applications of rectifiers it can be assumed that the voltage drop in the arc in vacuum decreases with increasing current, and the load characteristic is therefore similar to that of an over-compounded d-c. generator. From the above, it can easily be seen that rectifiers feeding the same bus-bars and connected in parallel to the same source of alternating current may not operate satisfactorily. To meet this condition, a sufficiently large inductance has to be inserted in the anode circuit of each rectifier so as to obtain a suitable load characteristic which assures satisfactory parallel operation of each cylinder over a given range of load. For instance, a correctly dimensioned choke coil can be used to obtain such an inductance. Incorporating the arrangement of the connections shown in Fig. 17B, the inductance or the flux set up in the choke coil can be limited to that part produced by the difference in the anode currents. The same

effect can be obtained by utilizing that part of the main transformer inductance which corresponds to the stray field, by using either a separate transformer for each rectifier, or a double six-phase arrangement, as given in Fig. 17A and C, respectively. However, the inductance set up in this way must be large enough to impress such a high voltage across the electrodes of a rectifier working in parallel with others but not taking a share of the load which will force it to pick up some of the load. The actual arc voltage, therefore,

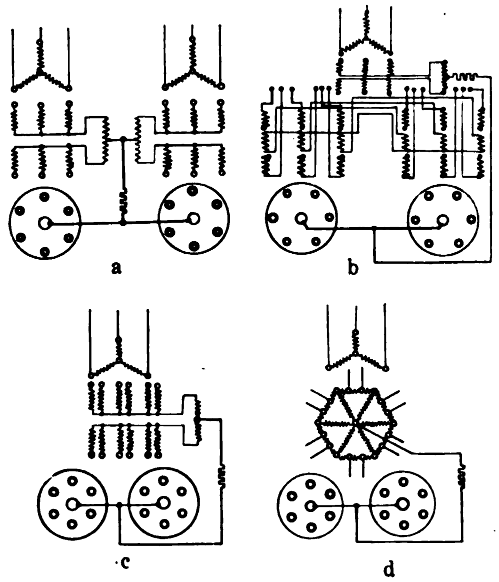

FIG. 17 A, B, C, D,—DIAGRAMS OF CONNECTIONS OF TWO RECTIFIERS IN PARALLEL

is less than the ignition voltage, and when several rectifiers are operating in parallel the unit having the lowest ignition voltage consequently picks up the load before the others. The voltage drop necessary for the operation outlined above cannot efficiently be obtained by means of ohmic resistance, and therefore methods such as those mentioned above for inserting an inductance into the anode circuit had to be developed so as to produce a satisfactory characteristic. As soon as all the rectifier units are taking their share of the load, their parallel operation is subject to the general conditions already stated. For comparison, all the methods of connection used to effect the desired characteristic for rectifier plants with more than one cylinder are given below, and are illustrated in Fig. 17A, B, C, D. In Fig. 17A, the effect is produced by making use of the leakage field of the main transformer; in Fig. 17B, by inserting a choke coil; in Fig. 17C, by means of the leakage field of the secondary winding only; and finally, in Fig. 17D, by doubling the number of phases on the secondary side.

As already pointed out, it is also essential that each unit take a proportionate share of the load when working in parallel. Two units are assumed to have falling-load characteristics E_1 and E_2, illustrated in Fig. 18. In can easily be seen that the distance between the two points of intersection of any horizontal straight line with the characteristics of the two sets gives the total current, I, supplied. The distance from the middle vertical line to the points of intersection gives the currents supplied by sets No. 1 and No. 2, respectively. The voltage of the two parallel working units is indicated by E. From this curve it is evident that an increase of the total load will be distributed according to the slope of the load characteristic.

It is sometimes desirable to have a rectifier working in parallel with rotary converters or motor generators. The efficiencies of the two latter types of converters are lower at overloads and at partial loads than the efficiency of the rectifier. In order to obtain, therefore, a good annual average efficiency for the plant, it is desirable to design these two types of converting devices for such load characteristics that in parallel operation the rotary converter or motor generator is always working at practically full load, while the fluctuating peaks are taken care of by the mercury arc rectifiers. Assuming that the load characteristic of the motor generator is shown on the right-hand side of Fig. 18, and the load characteristic of the mercury arc rectifier on the left-hand side, it is evident from the figure that the rectifier will take by far the larger share of a given increase in load.

Efficiency and Power Factor. Apart from other considerations, the outstanding electrical characteristic of the rectifier is its efficiency, which remains nearly constant at all loads; but to obtain the true commercial efficiency we must include all losses between the high-tension terminals of the transformer and the d-c. busbars. These losses are the losses in the transformer, excitation equipment, vacuum pump, and reactance coils. The constant efficiency of the rectifier alone is due to the drop in the arc being approximately constant

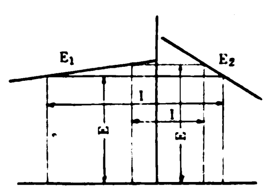

FIG. 18—PROPORTIONATE SHARE OF THE TOTAL LOAD BETWEEN A RECTIFIER AND A MOTOR GENERATOR

under all load and pressure conditions. This drop varies roughly between 16 and 23 volts according to the size of the rectifier, and is influenced by the vacuum to which it is directly proportional. The actual amount of watts dissipated in the rectifier is, therefore, simply the total drop multiplied by the current for any particular load, which gives a constant efficiency under all conditions. Thus when operating at 500 volts, direct current, the efficiency of the rectifier is represented by

$$\frac{500}{500 + 20} = 95.5 \text{ per cent.}$$

These indications show that the higher the d-c. voltage, the better will be the efficiency. For voltages up to 8000 volts, efficiency curves are plotted in Fig. 19A.

The over-all efficiency over the whole working range for 600-, 1500-, 300-, and 500-volt rectifiers of standard types is shown in Fig. 19B.

In general the power factor varies between 90 and 95 per cent. Reference was made to this under

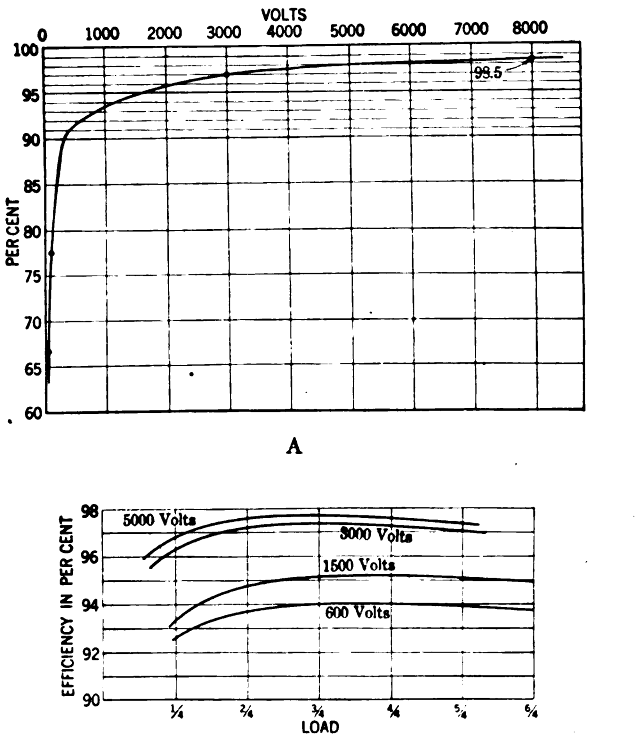

FIG. 19A,-B—OVER-ALL EFFICIENCIES OF RECTIFIERS FOR VARIOUS VOLTAGES

"Theory" and since it depends to a great extent on the external circuit further considerations are omitted.

Overloads. It is the very high momentary overloads that the rectifier can deal with that makes it preeminently suited for traction conditions where the average load is below full load. The consequence of this is that rather smaller normally rated sets can be employed than if, for instance, rotary converters were used.

Traction rotaries must necessarily be amply rated; otherwise commutator trouble will be experienced under very heavy overload or short-circuit conditions. Sometimes this measure does not do, and some special schemes of load protection have to be employed.

Extensive load and short-circuit tests on rectifiers showed that practically any overload can be handled for a certain time with a complete absence of any bad effects on the rectifier proper.

As there are no moving nor wearing parts, the life of the rectifier is still unknown as none of the rectifiers installed more than 12 years ago have shown any signs of deterioration as yet. The arc takes place in a vacuum, and therefore there is not any appreciable chemical effect on the anode or on the cylinder. No change either in the size or the shape of the anodes or of the inside surface of the cylinder that would in any way affect the operation of the rectifier could be observed. On the contrary, experience has shown that the longer the rectifier is in operation the better are its efficiency and its overload characteristic. The vacuum pump runs for such brief periods of time, and so infrequently, that the wear on its moving parts is negligible, while the development of the a-c. ignition has done away with any other rotating parts.

ADVANTAGES OVER ROTARY CONVERTERS

The floor space usually occupied by rectifiers is about the same as that required for rotary converters for d-c. voltages up to about 600 volts. Above that, the space required is considerably less. Special foundations are not required for any voltages except what is needed to bear the stationary weight. For this reason, and due to the fact that the operation of the rectifier is noiseless, new substations need only be of the lightest

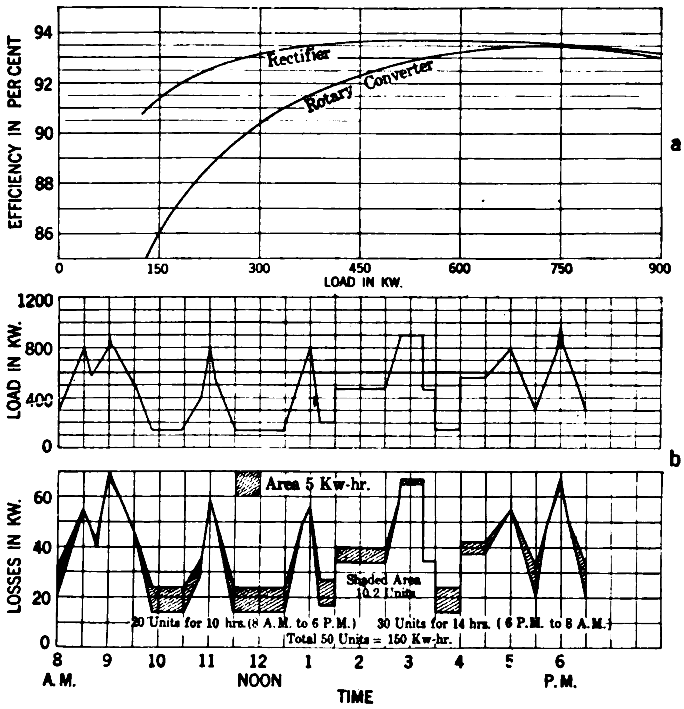

FIG. 21A—EFFICIENCY OF A 600-VOLT 600-KW. ROTARY CONVERTER AND MERCURY ARC RECTIFIER

B—LOAD CHART AND REDUCTION IN LOSSES BY THE USE OF MERCURY ARC RECTIFIERS INSTEAD OF ROTARY CONVERTERS

construction, and substations can, therefore, often be placed in locations that would not be at all suited for the installation of rotating machinery because of the vibration and noise.

Starting. Among the most striking advantages of the mercury arc rectifier over the rotary converter is the simplicity of the starting procedure. It takes a few seconds only to ignite the arc and put the rectifier

into service. This makes it preeminently adapted to automatically controlled substations. Since a rectifier has no standby losses, like a rotary converter, it can be generally left connected to the high-voltage supply, and in case of a short circuit at the primary side of the transformer, the rectifier disconnects itself from the network at the moment the arc extinguishes, and it will pick up the load as soon as the a-c. voltage is restored. However, even in manually operated substations, the attendance is greatly reduced, as will be explained at length later on.

Efficiency. To illustrate what the superiority of the rectifier efficiency really means, especially the efficiency at partial loads, a typical case of an actual railroad in the United States has been taken and the annual saving effected worked out on the basis of the daily-load curve. The curve in Fig. 21A shows the comparative efficiency of mercury arc rectifiers and rotary converters for 600-volt direct current. The conservative efficiency curves do not alter the comparative losses of the two classes of equipment nor the saving effected. The difference in the losses for the two sets is represented by the shaded area between the two lower curves of Fig. 21B and if this is averaged over 24 working hours it will be found that the losses of the rotary converter exceed those of the rectifier by about 125 kw-hr., representing, at a current cost of one cent per kw-hr., an annual saving of approximately $450 for a 600-kw-hr. mercury arc rectifier substation which represents half the interest on the investment required for such a substation.

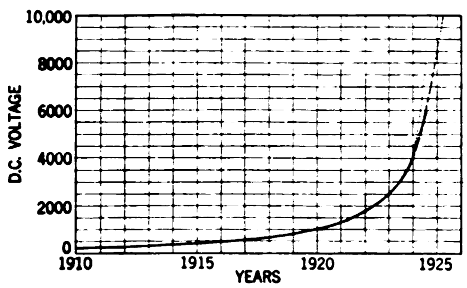

FIG. 22—MAXIMUM D-C. VOLTAGES OF RECTIFIER INSTALLATIONS IN SERVICE AND IN LABORATORY TESTS

As shown in Fig. 19A, the efficiency of a rectifier increases with the voltage; so these savings would increase appreciably at the high voltages. But even at the comparatively low voltage for which the above figures were computed the saving is worth considering. For a d-c. voltage of 1500 volts the annual saving would be over $1000.

As d-c. motors for terminal pressures of 2000 volts can be built to operate with perfect satisfaction, there is no reason why d-c. line pressures of 4000 volts cannot become widely adopted for railway service. In fact, the Torino-Lanzo-Ceres Railway in Italy has already been using that voltage for some time, and has obtained the best kind of service from its rectifier.

Needless to say, such voltages would be impracticable with rotary converters. The increase in the voltages on the d-c. side successfully used with rectifiers during the past 15 years is shown by the heavy line in Fig. 22, while the broken line shows the voltages which have been tested successfully at long trial tests, and the light dotted line, the voltages obtained during short laboratory tests. Following the extension of the voltage curve, it may be concluded that the next few years will possibly give us rectifiers furnishing direct current at pressures suitable for high-power transmission.

Another advantage of note is the fact that for the parallel operation of rectifiers there is no elaborate synchronizing procedure required. Since polarity indicators are also not needed, another possible source of trouble is eliminated. These facts again decrease the amount of special equipment necessary for an automatically or remotely controlled substation, while in a manually operated substation the attendant's duties are further reduced.

Automatic Control. The equipment for the full automatic operation of mercury arc rectifier substations costs less than half as much as for a rotary converter substation of the same capacity. Not only is the equipment cheaper, but because it is also simpler a better operation is assured.

The automatic operation of the vacuum pump is likewise an important advantage of the rectifier equipment. The vacuum gage previously described opens and closes the pump-motor circuit independently of the operation of the rectifier set itself, and always maintains the vacuum at the proper stage for immediate starting.

Making allowance for interest, depreciation, and taxes on the additional investment required for full automatic control of rectifier substations, and taking into consideration the salaries for high grade inspectors to look after the automatic equipment periodically, there will be effected a saving of $500 per year even in a small substation of only 600-kw. capacity.

Another great advantage accruing from the use of mercury arc rectifiers is the fact that changes in voltge can be made without any change in the rectifier. For instance, a railroad equipped for using 600-volt direct current can be changed to 1200-volt direct current merely by changing the connections of the transformers, and making no changes whatever in the rectifiers. Needless to say, this could not be done with rotary converters. Furthermore, the additional traffic that can be handled by making this change would represent another great advantage, all without any extra cost except the slight additional expense of having the transformers equipped with taps for making the change in the connections. As mentioned before, these rectifiers are able to withstand short circuits for a few moments without any harm, and can stand the severest overloads, taking instantaneously currents of even three times the normal value.

As an example of the short-circuit current one of the high-voltage rectifiers is capable of dealing with, it may be mentioned that a rectifier the normal capacity of which is 1800 volts and 400 amperes successfully passed a momentary current of 8700 amperes and was able to resume operation immediately upon clearing the short circuit. Sixty similar short circuits were applied within two days, after which the rectifier was opened and found to be in precisely the same condition as when sealed prior to these tests. In another instance, 10 short circuits were applied at one-minute intervals, and again there were no deleterious effects.

As mentioned under "Operation," the wear on the rectifiers is practically negligible.

The author gratefully acknowledges the valuable suggestions and assistance of Mr. Harold Winograd.

Abridgment of

Law of Magnetization

BY S. L. GOKHALE[1]

Member, A. I. E. E.

Synopsis.—*The purpose of the study which constitutes the subject matter of this paper was to investigate the reliability of Frolich's law of magnetization near saturation.*

For the last forty years, Frolich's law has been accepted as the most reliable expression representing the relation of magnetizing force to the magnetic induction produced thereby in ferro-magnetic materials. In the course of the study it was found that the law is not as reliable as it is generally believed to be, particularly for purpose of computation of saturation value. It was also found in the course of the same study that this part of the curve follows the law,

$$B - H = S\,(1 - b\,e^{-aH}) \quad . \; . \; . \; (\textit{equation } \mathbf{30\text{-}2})$$

more closely than any other law yet formulated. This law and Frolich's law are both in harmony with Weber's theory of molecular orientation. (See equations **24, 25, 26**).

---

1. Purpose of the Investigation and Plan of Presentation of Results

The progress of scientific and industrial development of production, distribution, and control of electrical energy depends very largely on the knowledge and understanding of the laws representing the relation of electric current to magnetism. During the last hundred years, various attempts have been made to obtain correct information about these laws. The analytical study and experimental work which constitutes the subject of this paper is one more effort toward the same goal; it is limited to a study of the law of magnetization for flux density in the neighborhood of saturation. Stated symbolically, the subject of this investigation is the equation,

$$B = F\,(H) \qquad (\mathbf{1})$$

and the problem in hand is the determination of the form of the function $F\,(H)$ and its properties. For reasons to be explained later, the form of the problem is slightly modified in the course of the study. (See § 3, equation **4**, and § 9, equation **23**.)

The plan of presentation of results which is followed in this paper is:

Nomenclature and symbols, with illustrative curves. Attention is directed to characteristic peculiarities of curves which occupy an important place in the subsequent argument.

Study of Ewing's conception of intrinsic induction, and of Weber's theory of molecular orientation, as a ground work for formulating a law of magnetization. (§ 3, 4; equations **4**, **6**).

Presentation of Frolich's law as a hypothesis in relation to Weber's theory. (§ 5, equation **7**.)

Study of different forms of Frolich's law, with a view to formulate some crucial equations whereby the validity of Frolich's law can be tested. (§ 5, 6, 7, 20; equations **7**, **9**, **11**, **12**, **17**, **32** and **33**.)

Further study of Weber's theory, as groundwork for equation of progress near saturation. (§ 8, 9; equations **22**, **23**).

Presentation of Frolich's law, as a hypothetic equation of progress. (§ 10, equation **24**.)

Experimental study of a curve of incremental permeability and reluctivity. It will be shown that the form of the observation curves does not support Frolich's law, but that on the contrary, its indications are in favor of Lamont's equation of progress. (§ 11, Fig. 3-1, equation **26**.)

(Supplement, § 20, Fig. 3-3, -4, equations **32**, **33**).

Law of latent induction ($\log \gamma = f - g\,H$) is derived as a corollary to Lamont's equation of progress. (§ 11, equation **29**.) This leads to the equation of magnetization, $B - H = S\,(1 - b\,e^{-aH})$, referred to in the synopsis. (Equation **30-2**.)

Study of saturation value and of $\beta\,H$, $\beta\,\mu$ and $H\,D$ curves for standard sheet steel. A study of these curves shows, first, that the magnetization curve for this material does not follow Frolich's law, and second, that for the part of the curve above $H = 300$, it follows the law $\text{Log}\ \gamma = f - g\,H$. (§ 12, 13, 14.)

---

1. General Engineering Laboratory, General Electric Co., Schenectady, N. Y.

Presented at the Annual Convention of the A. I. E. E., at White Sulphur Springs, W. Va., June 21-25, 1926.

Study of H ρ curve. The apparent straightness of the H ρ curve seems at first sight to support Frolich's law, but a closer study of the curve reveals that this is due to its insensitive character, and proves that it has no evidential value (§ 15, equation **31-2**).

Corroborative evidence from tests on other typical samples (§ 16).

Further corroborative evidence from tests at the Bureau of Standards. (§ 17, Fig. **12-2, -4.**)

Practical application of both laws for purpose of extrapolation beyond the limits of test (§ 18).

Summary of conclusions.

Tables of data and curves.

The scheme of numbering the tables and curves is such that all figures with a common group number refer to tables with the same group number. The sub-numbers have no significance; they are used merely as a convenient mark for subdivision of the group. In view of the difficulties due to the large number of figures necessary to illustrate the various points of the argument, a few curves are selected for publication. Other curves will be available in the form of blue prints, for anyone who desires to study the results farther than they are given in this paper.

Necessary references to all curves, including those that are not published, will be found in the tables. References to published curves only are given in the body of the text, each in its proper place.

2. Nomenclature and Symbols

The following symbols are used in this paper:

B Total induction, or flux density (gausses).

β Intrinsic induction, or flux density (gausses).

H Magnetizing force, (gilberts per cm.: briefly g).

H Spatial induction, (gausses, See par. 3, note 1).

S Saturation value, *i. e.*, limiting value of β.

γ Latent induction, ($= S - \beta$). (See §4, 8).

μ Intrinsic permeability ($= \beta/H$, not $= B/H$).

ρ Intrinsic reluctivity ($= H/\beta$).

D Distribution ratio ($= \beta/\gamma$).

μ' Transformation rate ($= - d\gamma/dH$, or $d\beta/dH$); also called incremental permeability.

ρ' Incremental reluctivity, ($dH/d\beta$).

i_1 First inflection of β μ or H ρ curves.

i_2 Second inflection of β μ or H ρ curves.

a Coefficient of permeability ($= \mu/\gamma$) when used with reference to Frolich's law in its various forms (equations **7**, **8**, **9**, **12**, **16**, etc.).

a Coefficient of incremental permeability ($= \mu'/\gamma$) when used with reference to Lamont's equation of progress, and other equations derived from it. (Equation **27**).

σ Coefficient of reluctivity ($= 1/S$).

α Initial reluctivity ($\alpha = \rho - \sigma H$). This quantity is also defined as $\alpha = 1/aS$. (See equations **10** and **11**).

h Coefficient of magnetic hardness ($h = 1/a$) when used with reference to Frolich's law (see equation **13**).

Curves are designated by joint use of the variables involved, for example, β H, β μ, H ρ curves; when one of the variables is logarithmic, a comma is inserted, for example H, log γ curve.

For illustration of these symbols see Fig. 1.

NOTES: The symbol H is used in two senses but this ambiguity does not lead to any inconvenience or mis-

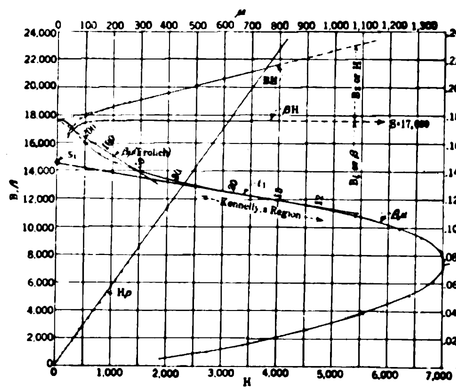

FIG. 1-1—SILICON STEEL (SAMPLE NO. R437-6)

understanding, as the context is clear in all cases. The same remark applies to the symbol a.

The symbol μ, in the usual sense of B/H, is not used in this paper.

The symbol ρ, in its original sense of H/B, is not used in this paper.

The numerical figures on the β μ curve refer to the

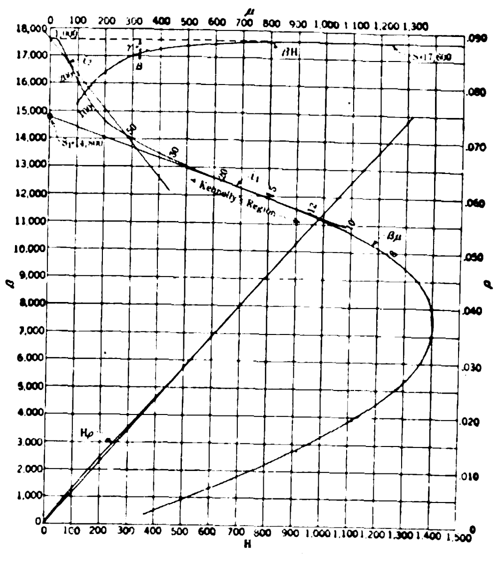

FIG. 1-2—MAGNIFIED SECTION OF FIG. 1-1

values of H for the corresponding points. The straight line drawn in relation to the β μ curve is a hypothetic β μ curve for Frolich's law, that is, the β μ curve which would be represented by this straight line if the material followed Frolich's law, within the limits indicated. (Fig. 1-1, -2, -3.)

In relation to the reluctivity curve, the straight line passing through the origin is the ideal reluctivity curve,

that is, a curve for a hypothetical sample of material having the same saturation value as the test sample but having no magnetic hardness, so that the material is supposed to be saturated from the s art. (Fig. 1-1, -2, -3.)

In studying the various curves, the following characteristics should be noted; their significance will be explained later.

(a) The β H curve has the appearance of a hyperbola, asymptotic to the saturation line (Fig. 1-1, -2, -3).

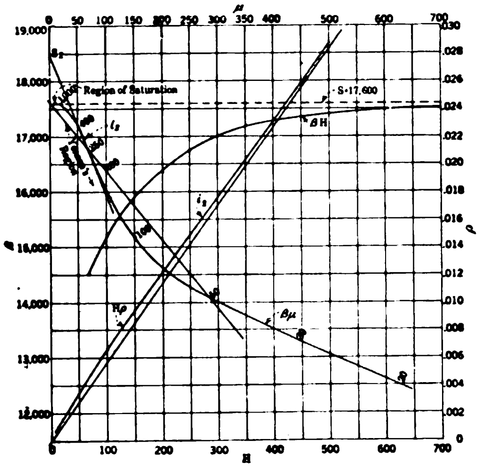

FIG. 1-3—MAGNIFIED SECTION OF FIG. 1-2

It will be shown later that the curve is not truly hyperbolic.

(b) For values of H above a certain limit, ($H = 50$ approx.), the H ρ curve appears to be almost a perfect straight line (Fig. 1-1, -2, -3). Even below $H = 50$, the curvature is scarcely noticeable.

(c) For corresponding values of H, the β μ curve is not straight. It contains three straight sections, *viz.*, regions of Kennelly, Yensen, and saturation. (Fig. 1-1, -2, -3.) For further discussion on this point, see §14.

(d) The H D curve is not straight; it has the appearance of an exponential curve. The corresponding logarithmic curve is comparatively straight; in the particular case selected for illustration, the logarithmic curve seems to be made up of two separate straight lines, with a seemingly abrupt bend at $H = 370$ (Fig. 1-6).

3. EWING'S CONCEPTION OF INTRINSIC INDUCTION

Prior to the year 1890, the various laws of magnetization propounded by several physicists were equations of the form $B = F(H)$ or other equations derived therefrom. In 1890, Prof. Ewing showed that the induction in all ferro-magnetic material could be conceived as made up of two components, each following its own characteristic law.

$$B = B_s + B_i \quad (2)$$

where

$$B_s = F_1(H) = H$$

and

$$B_i = F_2(H)$$

NOTES: B_s is the spatial induction, that is, induction in the space as a magnetic property of the space irrespective of the magnetic character or condition of the material occupying that space. It is supposed to follow the very simple law $B_s = H$. (See Fig. 1-1).

B_i is the intrinsic induction which depends on, and is an undetermined function of, H; it is signified by the symbol β in this paper. (See Fig. 1-1.)

B is the resultant induction in the magnetic material. Using the notation of §2, Ewing's conception is

$$B = H + \beta \quad (3)$$

The problem of determining the law of magnetization is thus reduced to a determination of the equation,

$$\beta = F(H) \quad (4)$$

In view of the fact that Ewing's conception is now generally accepted, it is considered necessary to revise the laws of Lamont, Frolich, etc., and regard them as referring to β, although in their original form they referred to B.

4. WEBER'S THEORY OF MAGNETIZATION, AND CONCEPTION OF LATENT FLUX

According to Weber's theory, as modified by Ewing, all magnetic material consists of molecular magnets; the question regarding the cause of magnetism of the molecules is irrelevant for our present purpose, and is therefore left out of consideration in this paper.

The process of magnetization is merely a process of orientation of the molecules.

In the non-magnetized condition the molecules form a large number of small groups, each group making a small but complete magnetic circuit.

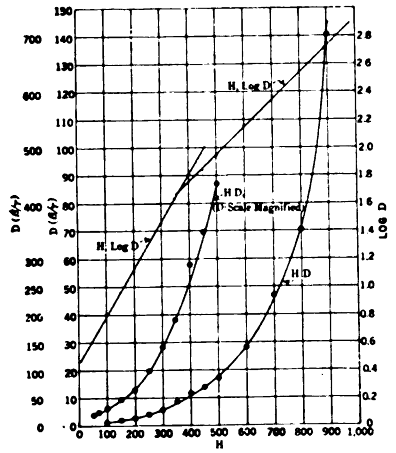

FIG. 1-6—H D AND H LOG D CURVES

The molecules in each group are held in their place by magnetic forces which originate in the molecular magnets of that group as well as of neighboring groups.

When a magnetizing force is applied to the magnetic material, each molecular magnet acting as a compass needle tends to turn around and place itself in a line parallel to the magnetizing force. This tendency is partly opposed by the counteracting magnetic forces of the neighboring molecules.

The function of the magnetizing force is therefore merely to determine the configuration of the molecules. For each configuration there is a certain magnitude of H necessary to produce it.

The total flux of the oriented molecules across any section of the magnet is the manifest flux, and this flux, divided by the area of that cross-section, is the manifest induction; it is represented by the symbol β.

The total flux of the unoriented molecules across the same cross-section is the latent flux; it is made up of two groups of flux lines in opposite directions making an algebraic total of zero lines. The total number of these lines reckoned without consideration of direction is the latent flux, and this flux divided by the sectional area of the whole magnet is the latent induction; it is represented by the symbol γ.

The total intrinsic flux in a magnet across any section is the aggregate of flux lines of all molecules irrespective of the direction of the lines. This is a constant quantity not dependent on the magnetizing force, being determined only by flux in each molecule and by the total number of molecules in the plane of the cross section; it is represented by the symbol S.

The function of the magnetizing force is to establish a

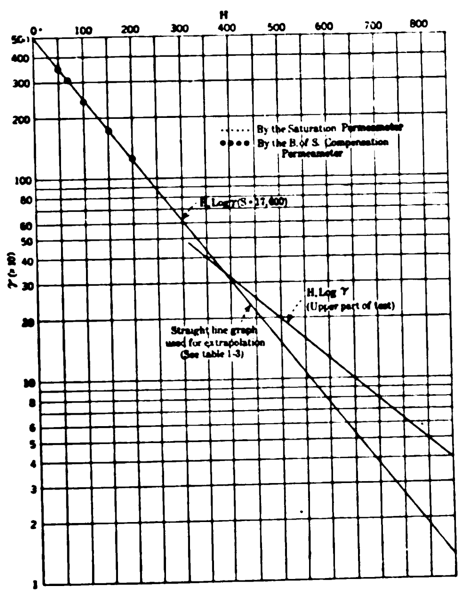

FIG. 1-7—H γ CURVE

configuration of the molecules and therefore the distribution of S into its two components β and γ. (See Fig. 1-2.)

Weber's theory may therefore be stated analytically by the equations,

$$\beta + \gamma = S \tag{5}$$

and

$$\beta / \gamma = F\,(H) \tag{6}$$

the form of the function H being undetermined for the present.

5. FROLICH'S LAW: HYPOTHETIC EQUATION OF DISTRIBUTION RATIO

We have seen that according to Weber's theory $\beta/\gamma = F\,(H)$, the form of the function being yet undetermined. If at this point we assume that the distribution ratio is not only a function of H but is directly proportional to H, we arrive at the equation,

$$\beta/\gamma = a\,H \tag{7}$$
$$= H/h$$

where $h = 1/a$,

or

$$D = a\,H = H/h \tag{7-2}$$

This equation may be called Frolich's hypothesis be-

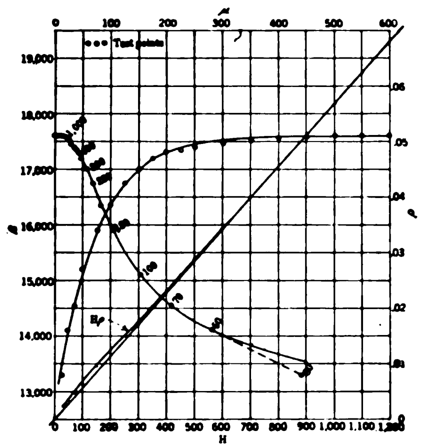

FIG. 1-8—RECONSTRUCTION OF CURVES BY LOGARITHMIC LAW

cause it is implied in Frolich's law. It has not been explicitly stated in this form by Dr. Frolich or by any one else. Substituting for γ its equivalent $S - \beta$, we get

$$\beta/\gamma = a\,H$$

$$\therefore \beta/(S - \beta) = a\,H \tag{8}$$

$$\therefore \qquad \beta = S\,.\,a\,H/(1 + a\,H) \tag{9}$$

$$= S - S/(1 + a\,H) \tag{9-2}$$

This is Frolich's law (*E. T. Z.*, 1886, p. 164).

Equation (**9**) can also be expressed as

$$\beta = \frac{H}{\dfrac{1}{a\,S} + \dfrac{H}{S}}$$

$$= \frac{H}{\alpha + \sigma\,H} \tag{10}$$

where

$$\alpha = 1/a\,S, \text{ and } \sigma = 1/S.$$

This is another form of Frolich's law (*E. T. Z.*, 1882, p. 71).

From equation (**10**) we obtain

$$H/\beta = \alpha + \sigma\,H$$

or

$$\rho = \alpha + \sigma\,H \tag{11}$$

or

$$\rho = (H + h)/S \tag{11-2}$$

This equation is known as Kennelly's law. It was formulated first by Prof. Fleming, who derived it as a corollary to Frolich's law, (J. I. E. E. *Trans.*, 1886, p. 569); second by Dr. Kennelly, who derived it independently of Frolich's law, empirically from a study of the published data of Ewing, Rowland and Du Bois, (A. I. E. E. TRANS., 1891, p. 503-517); and third by Dr. Steinmetz, who derived it also as an empirical law from the study of data published by Dr. Corsepious, (*E. T. Z.*, 1892, p. 203).

From equation (**8**) we also obtain directly

$$\beta/H = a\,(S - \beta)$$

or

$$\mu = a\,(S - \beta) \tag{12}$$

or

$$\mu = \gamma/h \tag{12-2}$$

This is Bosanquet's law, (*Electrician* 1886, p. 247). Equation (**12**) may also be derived directly from equation (**11**) by purely algebraic process involving no other equations except the defining equations,

$$\mu = \beta/H$$
$$\rho = H/\beta$$
$$\alpha = 1/a\,S$$

and

$$\sigma = 1/S$$

The relation of equation (**12**) to equation (**11**) is not dependent on their relation to equation (**7**) or (**8**) or to any other hypothesis. From this it follows that if any part of the $H\ \rho$ curve is straight, the corresponding part of the $\beta\ \mu$ curve must also be straight.

Again, starting with equation (**9**)

$$\beta = S\,.\,a\,H/(1 + a\,H)$$

and using a symbol $h = \dfrac{1}{a}$ (see equation **7-2**), we get

$$\gamma = S\,h/(H + h) \tag{13}$$
$$\beta = S\,.\,H/(H + h) \tag{14}$$
$$= S - S\,h/(H + h) \tag{15}$$

NOTE: The relation of equations (**7-2**), (**9**), (**11-2**), (**12-2**), (**13**), (**14**), (**16**) and (**17**) can be easily demonstrated geometrically with the help of Fig. 2-1. For example,

$M\,P/P\,N = O\,M/N\,Q$ or $\beta/\gamma = H/h$, equation (**7-2**).

Again $M\,P/O\,S = O\,M/S\,Q$, or $\beta/S = H/(H + h)$, equation (**14**).

Equations (**13**), (**14**) and (**15**) are equations for Frolich's law in its analytical form. They lend themselves easily to computation of β and γ for any value of H. Equation (**15**) is preferred in this paper in the preparation of the several tables. For example, see Table II. The several equations given above lead us to expect that

1. If Frolich's law be true for the entire curve above any value of H, the corresponding parts of the $H\ \rho$, $\beta\ \mu$ and $H\ D$ curves should be straight lines, as the corresponding equations are all of the first degree. (See equations **7-2**, **11** and **12**. Fig. 2-1.)

2. If Frolich's law be true only between certain limits and not true above and below that limit, the $H\ \rho$ and $\beta\ \mu$ curves should be straight between those limits, but the $H\ D$ curve should not be straight even between those limits if the true saturation value determined by measurement be used as a basis of computation, unless the value of S indicated by the straight part of the $H\ \rho$ or $\beta\ \mu$ curve happens to be the true saturation value. No concrete instance of such exceptional coincidence has yet been observed.

3. In no case is it possible to find a particular part of the $H\ \rho$ curve straight unless the corresponding part of the $\beta\ \mu$ curve is also straight.

These three curves, *viz.*, the $\beta\ \mu$, $H\ \rho$ and $H\ D$ curves, are therefore three practical tests whereby the truth of Frolich's law for any part of the $\beta\,H$ curve may be

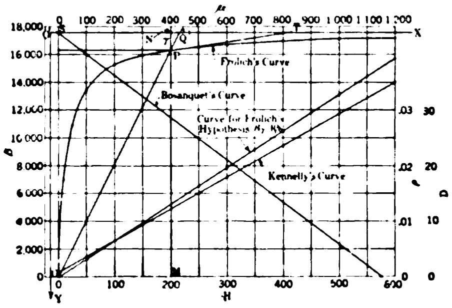

FIG. 2-1—FROLICH'S LAW AND COGNATE CURVES

The $\beta\ H$ curve is an equilateral hyperbola with asymtotes $O'\,X$, $O'\,Y$

$\beta = M\,P$	Then	$\beta/H = S/(H + h)$	Frolich's Law
$\gamma = N\,P$		$\beta/H = \gamma/h$	Bosanquet's Law
$H = O\,M = S\,N$		$H/\beta = (H + h)/S$	Kennelly's Law
$S = O\,S$		$\beta/\gamma = H/h$	Frolich's Hypothesis
$h = O'\,S = N\,Q$		$\beta/S = H/(H + h)$	
$H + h = O'\,N = N\,T = S\,Q$		$d\beta/d\,H = P\,N/N\,T$	
		$= r/(H + h)$	
		$= r^2/S\,.\,h$	Frolich's Equation of Progress

tested; two other practical tests will be described later. (See §6 and 20.)

6. FROLICH'S EQUATION OF PROGRESS AND EMERY'S LAW

By differentiation of equation (**12**), we obtain,

$$\mu' = \frac{a}{S}\,(S - \beta)^2 \tag{16}$$

$$= K\,(S - \beta)^2 \tag{17}$$
$$= \gamma^2/S\,h$$

where

$$K = a/S = 1/S\,h.$$
$$\therefore \mu = \gamma/H + h) \tag{17-2}$$

(See equation **13**.)

This is Frolich's equation of progress of magnetization. (*E. T. Z.*, 1886, p. 164.) By reintegration of equation (**16**), we get

$$\beta = S\,(a\,H + c\,S - 1)/(a\,H + c\,S) \tag{18}$$

or

$$\beta = S - S/(a\,H + c\,S) \tag{19}$$

where c is an undetermined constant of integration. This is Emery's law. (A. I. E. E. TRANS., 1892, pp. 209, 215.) In equation (**18**) or (**19**), if $c = 1/S$, the equation reduces itself to the form

$$\beta = S \,.\, a\, H/(1 + a\, H) \tag{9}$$

or

$$\beta = S - S/(1 + a\, H) \tag{9-2}$$

This is Frolich's law.

From Emery's law we have,

$$\beta/\gamma = a\, H + c\, S - 1 \tag{20}$$

According to Emery's law the distribution ratio expressed as a function of H is a straight line not passing through the origin except in the particular case where $c\, S - 1 = 0$ in which case Emery's law becomes Frolich's law; in either case it is a straight line. Equation (**16**) is an equation of first degree for μ' and second degree for β. Therefore, if Frolich's law be true, the corresponding curve should be a parabola with the vertex at the point S on the axis of β, and with its directrix parallel to the axis of β.

7. Study of Equations of Distribution Ratio (Equations 7 and 20)

We have seen that Frolich's law in all its forms, and even Emery's law, involves the hypothesis that the distribution ratio is a linear function of H. Such an assumption has no justification either theoretical or empirical. Fig. 1-6 shows the curve for distribution ratio for a selected sample of silicon steel.. This curve is certainly not a straight line. On the theoretical side we have against it the negative fact that no reason has yet been given to explain why the ratio β/γ should be a simple linear function of H. It is true that there is nothing inherently absurd in the assumption that the ratio of the components β and γ is proportional to magnetizing force; it does not conflict with Weber's theory, but neither is there anything in Weber's theory to justify or even to suggest that assumption; in fact even the form of the general equation (**6**), that is, $\beta/\gamma = F\,(H)$, does not express the fundamental nature of the phenomenon which would be better expressed by a differential equation of the form,

$$d\,\beta/d\,H = F\,(\beta, \gamma)$$

although the final result may be expressed in any convenient form, including the form,

$$\beta/\gamma = F\,(H)$$

NOTE: We have seen that the curve β/γ as a function of H is not straight, but has the appearance of an exponential curve corresponding to the equation $\beta/\gamma = e^{H}$. (See §2 par. d.) If this conjecture be correct, the curve for log β/γ should be a straight line. This expectation is found to be partly justified by Fig. 1-6. This point will be discussed more fully later. (See §13, equation **30-4**.)

8. Equation of Progress According to Weber's Theory

According to Weber's theory, the values of β and γ for any value of magnetizing force depend on the configuration which has been reached under the influence of that force, and which is therefore determined by the condition of equilibrium between the internal and external magnetic forces when that configuration is established. The internal forces are those due to the interaction of the magnetic poles of the molecules, from which it follows that the forces which oppose the change of configuration at any step in the process of magnetization are determined by the configuration itself. According to this conception, the process of magnetization is a progressive process made up of changes of configuration in successive steps, and is, at each step, accompanied by a transformation of a small part of the latent induction $d\,\gamma$ into an equal amount of manifest induction $d\,\beta$, under the influence of the incremental magnetizing force $d\,H$. The fundamental law of magnetization should therefore be an equation of the form,

$$d\,\gamma/d\,H = -\,F\,(\beta, \gamma) \tag{21}$$

or

$$d\,\beta/d\,H = F\,(\beta, \gamma) \tag{22}$$

Equations (**21**) and (**22**) are identical, being merely the negative and positive aspects respectively of the same transformation process. In formulating this conception, the transformation ratio $(d\,\gamma/d\,H)$ is expressed as a function of β and γ, but not as a function of H; this is because, according to the conception under discussion, the transformation of $d\,\gamma$ into $d\,\beta$ is brought about by the operation of the increment $d\,H$, not by the whole magnetizing force H. The function of the magnetizing force H is to establish the corresponding configuration by counteracting the opposing internal forces, and when that configuration has been reached the function is exhausted. Any further change in the value of β and γ is brought about by the incremental component of force $d\,H$, and the magnitude of this component necessary for unit change in γ and β is determined by the component of internal force which it has to oppose and overcome. This component of internal force is the result of, and therefore some mathematical function of, the configuration itself, that is, a function of β and γ; it follows therefore that the rate of transformation $d\,\gamma/d\,H$ must be fundamentally a function of β and γ but not of H. But since β and γ are themselves functions of H, it also follows that $d\,\gamma/d\,H$ is capable of being expressed as a function of H, although such an equation would not be the fundamental equation.

9. Equation of Progress Near the Saturation Limit

We have seen that $d\,\gamma/d\,H$ is a function of β and γ. (See equation **21**.) At this point, we can introduce a further simplification by limiting the problem to the part of the curve near saturation. As saturation approaches, the manifest component of flux β becomes practically constant. The corresponding oriented molecules are now practically in the final stage of orientation; their influence in opposing any change of configuration is

now practically constant irrespective of how great or how small that influence happens to be; this makes the transformation ratio depend on the γ component of S only, which is now practically the only variable in the function.

Thus we have the equation,

$$d\,\gamma/d\,H = -\,F\,(\gamma) \qquad \textbf{(23)}$$

the form of the function $F\,(\gamma)$ being yet undetermined; the determination of the function $F\,(\gamma)$ now becomes the main problem.

10. Study of Frolich's Equation of Progress

At this point we might make some assumption as to the form of the function $F\,(\gamma)$. If we assume $F\,(\gamma) = K\,\gamma^2$, we have

$$d\,\gamma/d\,H = -\,K\,\gamma^2 \qquad \textbf{(24)}$$

or

$$d\,\beta/d\,H = K\,(S - \beta)^2 \qquad \textbf{(25)}$$

This is Frolich's equation of progress (see equation **17**) wherein K represents the ratio of Frolich's constants, a/S, (see §6, equation **16**). The status of Frolich's law depends on the validity of the assumption

$d\,\beta\,d\,H = \dfrac{a\,(S-\beta)^2}{S}$. On the theoretical side no justification for this assumption has been given by Dr. Frolich or by any one else. On the empirical side, there is no experiment on record to demonstrate that the curve for incremental permeability as a function of β is a parabola such as is represented by the equation in question.

11. Form of Curve for Incremental Permeability and Equation of Latent Induction

In order to ascertain the validity of Frolich's assumption (Equation **16** or **24**), a sample of standard

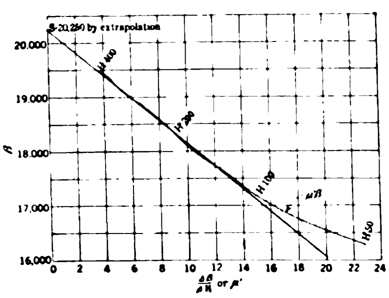

Fig. 3-1—Standard Sheet Steel Ring Curve of Incremental Permeability

steel in the form of a toroid ring was tested by the differential method. For details of test and result of measurement see Table III, Fig. 3. The curve plotted from test has certainly no resemblance to the parabola

representing the equation $d\,\beta/d\,H = \dfrac{a\,(S-\beta)^2}{S}$. Incidentally, we observe that the observation curve, though not perfectly straight, is very nearly a straight line for magnetizing forces above $H = 100$, and still more straight above $H = 200$. The test stops at $H = 400$; extrapolation of the curve indicates a saturation value of $S = 20{,}250$. (For true value of S, see next paragraph.) We might therefore follow the

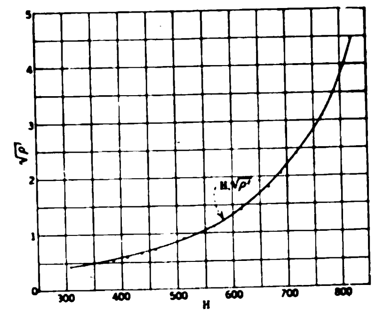

Fig. 3-3—Standard Sheet Steel Ring Curve of Incremental Reluctivity H as a Function of $\sqrt{\rho'}$

suggestion of this experiment and assume that the function $F\,(\gamma)$ in equation (**23**) is $a\,\gamma$.

This leads to the equations

$$d\,\gamma/d\,H = -\,a\,\gamma \qquad \textbf{(26)}$$

or

$$d\,\beta/d\,H = a\,(S - \beta) \qquad \textbf{(27)}$$

This is Lamont's hypothetical equation of progress. By integrating either of these, we have

$$\log_e \gamma = C - a\,H \qquad \textbf{(28)}$$

where C is an integration constant,

or

$$\log_{10} \gamma = f - g\,H \qquad \textbf{(29)}$$

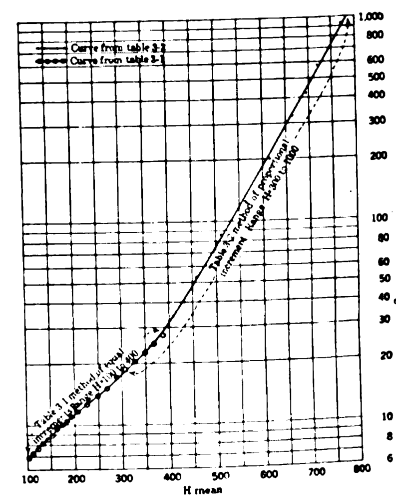

Fig. 3-4—Curve of Incremental Reluctivity H as a Function of Log ρ'

From equation (**28**), we get

$$\beta = S\,(1 - b\,e^{-aH}) \qquad \textbf{(30)}$$

where $b = e^c/S$,

or

$$B - H = S\,(1 - b\,e^{-aH}) \qquad \textbf{(30-2)}$$

This is the law of magnetization referred to in the synopsis.

Equation (**30**) is the same as Lamont's equation in form, but differs from it in the limitations which are implied in equations (**26**) and (**30**) but not recognized by Lamont, *viz.*, that the equation is true for parts of curve near saturation only (See par. 9). Lamont assumes that the equation is true for all values of H including $H = 0$, which makes $b = 1$; Lamont's equation therefore takes the form,

$$\beta = S\,(1 - e^{-aH}) \qquad \textbf{(30-3)}$$

This equation has no experimental support.

12. Law of Magnetization for Standard Sheet Steel

In order to ascertain the reliability of the extrapolation method based on the assumption $d\,\gamma/d\,H = -\,a\,\gamma$, the ring referred to in the last paragraph was unwound and rewound for higher magnetizing force reaching up to $H = 1000$, if possible. (For details of test and result of measurement, see Table IV, Fig. 4). The sample seems to be saturated at $H = 650$, reaching the saturation value of $S = 20{,}200$, which is in very close agreement with that indicated by extrapolation,

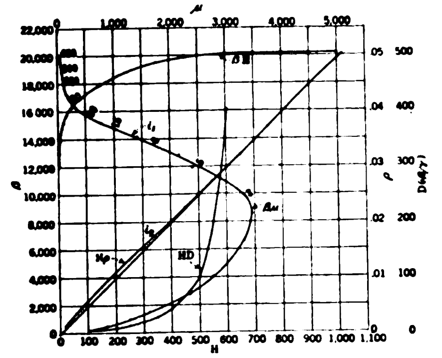

Fig. 4-1—Standard Sheet Steel Ring

viz., 20,250 (See Fig. 3). For magnetizing forces above $H = 300$, the observation curve is in very close agreement with the reconstruction curve representing the law, $\log\gamma = f - g\,H$; (see Fig. 4-4); it is not in as good agreement with the law $\beta = S\,a\,H/(1 + a\,H)$. (See Fig. 4-5.)

13. Curve of Distribution Ratio for Standard Sheet Steel

According to the equation (**7**), ($\beta/\gamma = a\,H$), the curve for distribution ratio should have been a straight line. The observation curve is certainly not straight, (Figs. 1-6, 4-1). On the contrary, the curve seems to be exponential, as it ought to be if equation (**30**) represented the true law of magnetization; for,

$$\beta = S\,(1 - b\,e^{-aH}) \qquad \textbf{(30)}$$

Then

$$\gamma = S\,.\,b\,e^{-aH}$$

Then

$$\beta/\gamma = (1 - b\,e^{-aH})/b\,e^{-aH}.$$

$$= \frac{1}{b\,e^{-aH}} - 1$$

$$= \frac{1}{b\,e^{-aH}} \text{ approximately as saturation approaches,}$$

or

$$D = e^{aH}/b \qquad \textbf{(30-4)}$$

or $\text{Log}_{10} D = p\,H + q$ (making due allowance for change of base). The corresponding observation curve

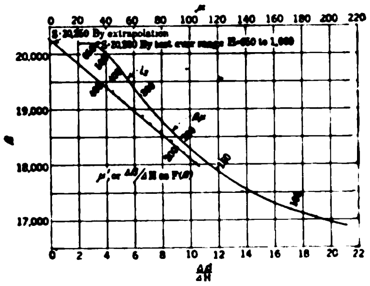

Fig. 4-2—Magnified Section of $\beta\mu$ Curve, Fig. 4-1 $\mu'\rho$ Curve from Fig. 3-1 Reproduced for Comparison

is approximately straight, showing that the distribution ratio is not a linear function of the magnetizing force as is required by Frolich's law, but nearly an exponential function as is required by the law of equations (**29**) and (**30**).

14. The Permeability and Reluctivity Curves

According to Frolich's law, equation (**12**), ($\mu = a\,(S - \beta)$, the $\beta\,\mu$ curve should be a straight line

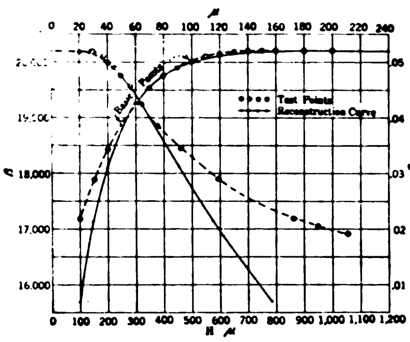

Fig. 4-4—Reconstruction of Curves by Log Law

intersecting the axis of β at the point S. The observation curve does not seem to fulfill this condition, (see Fig. 4-1, -2). For magnetizing forces above $H = 300$, the curve seems to follow very closely the law $\log\gamma = f - g\,H$. The complete $\beta\,\mu$ curve is not straight, but it has three straight regions.

1. First straight region, associated with the first inflection i_1 (Kennelly's region; see Figs. 1-1, 4-1).
2. Second straight region, associated with the second inflection i_2 (Yensen's region; see Figs. 1-3, 4-2).
3. Region of saturation.

The work of Dr. Kennelly was limited mostly to that part of the βH curve which corresponds to the first straight region, (see Fig. 5-2); and the work of Dr. Yensen was limited to the second straight region, (see Fig. 5-1). From the form of the $\beta \mu$ curve it is obvious that Frolich's law should hold true within the corresponding limits of H for each of these regions, but not for the whole curve above the first or even above the second region. The first and second regions can be

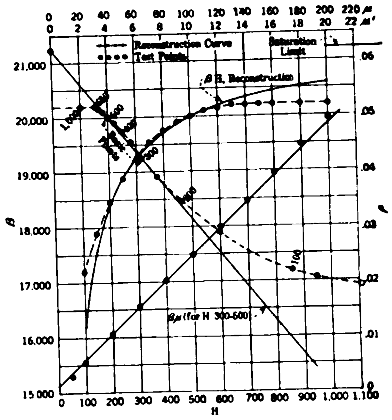

FIG. 4-5—RECONSTRUCTION OF CURVE BY FROLICH'S LAW ON THE BASIS OF YENSEN'S REGION

represented by the equations, $\mu = a_1 (S_1 - \beta)$, and $\mu = a_2 (S_2 - \beta)$, respectively, (see Figs. 1-1, -3), but it must be remembered that neither S_1 nor S_2 represent necessarily the true saturation value. In all cases observed thus far, S_1 is always less, and S_2 always greater, than S. (See Figs. 1-1, -2, -3; S_1 = 14,800, S_2 = 18,430, S = 17,600.) The curve for reluctivity as a function of H, *i. e.*, $H \rho$ curve, possesses all the characteristics of the $\beta \mu$ curve, but they are not so easily noticeable in the $H \rho$ curve, (see Figs. 1-1, -2; for points i_1 and i_2, see Figs. 1-3, 4-1, -2). The $H \rho$ curve seems to be almost a perfect straight line; in some cases, it seems to resolve itself into two straight lines connected by an apparently abrupt bend; in either case, the straightness is only apparent and misleading.

15. INSENSITIVE CHARACTER OF RELUCTIVITY ($H \rho$) CURVE

It has long been recognized that the reluctivity curves are always almost perfectly straight over a wide range although the corresponding parts of the $\beta \mu$ curves are not straight. (Kennelly: A. I. E. E., 1891, p. 531.) Theoretically, the $\beta \mu$ curve and the $H \rho$ curve are so related that if one of them be straight, the other must be straight also; the straightness of the $H \rho$ curve over a wide range is therefore anomalous, being mathematically impossible when the corresponding part of the $\beta \mu$ curve is not straight. The explanation of the anomaly lies in the insensitive character of the $H \rho$ curve in comparison with the $\beta \mu$ curve. The insensitive character of the $H \rho$ curve is inherent in the form of the function irrespective of the law of reluctivity.

This may be seen from the following analysis:

The insensitiveness of the reluctivity curve may also be demonstrated graphically by choosing for comparison two samples of magnetic material of nearly identical character. (See Table XII-III.) The differences between the two $\beta \mu$ curves are then easily noticeable, but the corresponding $H \rho$ curves are practically indistinguishable except near the upper end of the curves. Fig. 5-1 is a concrete example of insensitivity of the $H \rho$ curve. The data for this curve are taken from an experiment by Dr. Yensen (A. I. E. E. TRANS., 1920, p. 821). In the data as originally published, there appears to be a typographical error which becomes manifest in the βH and $\beta \mu$ curves but is scarcely noticeable in the $H \rho$ curve.

16. MAGNETIZATION CURVES FOR MAGNETIC METALS AND BINARY FERRIC ALLOYS

In view of the importance of the conclusions reached in the foregoing pages, it seemed advisable to extend the experiment to a variety of samples. The following list contains a few samples selected for purpose of demonstration; only toroid ring samples are included in this list.

1. Pure iron, electrolytic vacuum fused and vacuum annealed.
2. Pure nickel, 99.5 per cent nickel.
3. Pure cobalt, percentage not specified.

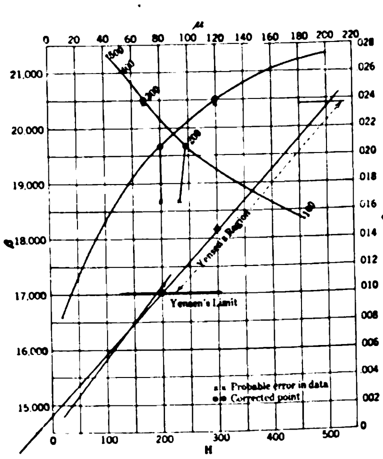

FIG. 5-1—YENSEN'S CURVE FOR 2 *N i* 204

NOTE: This sample was used by Mr. J. D. Ball in his well-known experiment: G. E. *Review*, 1916, p. 379.

4. Iron nickel alloy, 72 per cent nickel.
5. Iron cobalt alloy, 20 per cent cobalt.

For details of test and results of measurement see tables and curves in appendix.

A study of the curves shows that:

1. In all cases except cobalt, the samples are saturated well within the limits of test.
2. In all cases the complete $\beta \mu$ curve above the point of maximum permeability is not straight, but has all the peculiarities mentioned in par. 14, *viz.*, the two inflections and the three straight regions. In the case of

cobalt, the curve is incomplete but it demonstrates the first two straight sections.

3. The curve of distribution ratio is not straight as required by Frolich's hypothesis, but has the appearance of an exponential curve.

4. The βH curve by measurement is in closer agreement with the reconstruction curve according to the logarithmic law than with the reconstruction curve by Frolich's law. The same remark applies to the other derived curves, such as the $\beta \mu$ curve.

5. Below the second inflection, the βH curve does not follow the logarithmic law; according to the theory outlined above, this disagreement should be expected, for the rate of transformation is no longer capable of being represented by the simpler equation, $d \gamma / d H = - a \gamma$, but must be a more complex function involving both β and γ. (See equation **21.**)

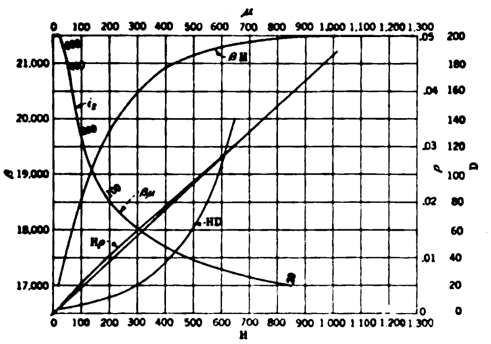

FIG. 12-2—ELECTROLYTIC IRON MAGNIFIED SECTION—TEST BY BUREAU OF STANDARDS

By way of further evidence in support of item (4), I may refer once more to Fig. 1, which has been obtained by the saturation permeameter. In this case also the βH curve is in closer agreement with the logarithmic law than with Frolich's law, (Fig. 1-8). Tests by the saturation permeameter run into several hundred samples. It is obviously not practicable to include them all in this paper, and I must therefore limit myself to the bare statement that in all cases the observation curve follows the logarithmic law much more closely than Frolich's law.

17. CORROBORATIVE EVIDENCE FROM TESTS AT THE BUREAU OF STANDARDS

Further evidence in support of the above findings will be found in the data from tests at the Bureau of Standards (See Table XII, Fig. 12). In this case the material under test was a group of samples of electrolytic iron carefully prepared by Dr. T. D. Yensen. The tests were made at the Bureau of Standards; both the material and the test results are of the highest order of reliability. The curves speak for themselves and need no further explanation.

18. PRACTICAL APPLICATION OF THE LAW LOG $\gamma = f - g H$

As a practical application of these conclusions, let us complete by extrapolation the incomplete βH curve for cobalt; the whole procedure is as follows:

19. SUMMARY OF CONCLUSIONS

We have found that:

1. According to Weber's theory of molecular orientation, the process of magnetization should be expressed fundamentally by an equation of progress of the form

$$d \gamma / d H = F_1 (\beta, \gamma)$$

and in its ultimate effect by the equation of distribution ratio of the form

$$\beta / \gamma = F_2 (H)$$

2. For the part of the curve near saturation, the equation of progress should be of the simpler form

$$d \gamma / d H = - F_1 (\gamma)$$

3. Frolich's law involves the assumption, fundamentally, that

$$d \gamma / d H = - K \gamma^2$$

and in ultimate effect that

$$\beta / \gamma = a H$$

This assumption has no theoretical justification or empirical support.

4. In the case of a toroid ring of standard sheet steel, it was found that for magnetizing forces $H = 200$ to 400, the progress of magnetization followed, approximately, the equation

$$d \beta / d H = a (S - \beta)$$

5. From the above equation, it follows that as saturation approaches, the magnetization should be expected to follow approximately the equation

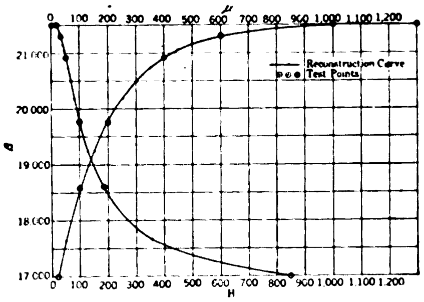

FIG. 12-4—RECONSTRUCTION OF CURVE BY LOG LAW

$$\log \gamma = f - g H$$

This expectation has been justified by subsequent verification (see next item).

6. For magnetizing forces above the second inflection of the permeability curve, the βH curve follows the law $\log \gamma = f - g H$ more closely than any other law yet formulated.

7. The part of the $\beta \mu$ curve above the point of

maximum permeability is not straight, but it contains three straight regions, *viz.*,

(a) The region of first inflection (Kennelly's region).

(b) The region of second inflection (Yensen's region).

(c) The saturation region.

8. It follows from this observation that a magnetization curve does not follow Frolich's law except in the first two regions mentioned above. The corresponding parts of the βH curve are segments of equilateral hyperbola corresponding to the equations

$$\beta = S_1 a_1 H/(1 + a_1 H)$$

and

$$\beta = S_2 a_2 H/(1 + a_2 H)$$

where S_1 and S_2 are the indicated saturation values corresponding to the two inflection regions. S_1 is always less, and S_2 always greater, than the true saturation values.

9. The part of the $H \rho$ curve above the point of minimum reluctivity appears to be very straight. The straightness of the $H \rho$ curve has been generally regarded as a conclusive evidence in favor of Frolich's law, but it has now been demonstrated that the straightness of this curve is only a geometric illusion, being caused by the insensitive character of the reluctivity function. The insensitiveness of the $H \rho$ curve has been proved analytically and demonstrated graphically. It follows therefore that the straightness of the $H \rho$ curve is misleading, and that the curve is therefore not reliable for purpose of drawing any conclusion as to the nature of the law of magnetization or for extrapolation of the βH curve. The $\beta \mu$ curve is a more reliable criterion, and the curvature of a $\beta \mu$ curve between any limits demonstrates conclusively the unreliability of Frolich's law for the corresponding range of the βH curve.

20. Incremental Reluctivity (Supplement)

In paragraph 11, reference is made to an experiment for determination of the incremental permeability $d\beta/dH$ as a function of β. The test stops at $H = 400$; all attempts to extend the test to $H = 1000$ have been unsuccessful. By slightly modifying the test procedure, it has become possible to determine the curve for ρ' or $dH/d\beta$ as a function of H for a range of $H = 400$ to 800. Differentiation of equations (9) and (29) leads respectively to equations of form

$$\sqrt{\rho'} = H + q, \text{ for Frolich's law} \quad \text{(32)}$$

$$\log \rho' = H + q, \text{ for logarithmic law} \quad \text{(33)}$$

From these equations it follows that for any range of H,

(a) If Frolich's law be true, the curve $H, \sqrt{\rho'}$ should be straight,

(b) If the law $\log \gamma = f - g H$ be true, the curve $H \log \rho'$ should be straight.

Figs. 3-3 and 3-4 represent graphically the result of a test and demonstrate that for the range $H = 400$ to 800, the $H, \sqrt{\rho'}$ curve is not straight, and that the $H \log \rho$ curve is straight, proving thereby that near saturation the βH curve follows the law $\log \gamma = f - g H$ far more closely than Frolich's law. For further details see complete pamphlet form.

TABLE I

4 per cent Silicon Steel: Sample No. R-437-6 (Ref. G. L. 39705-39, -41)

Note: This is a very unusual sample selected for purpose of illustration only because it combines in a single sample all the characteristic peculiarities that call for a demonstration. The sample is not a representative of the grade of steel to which it nominally belongs. Tests above H-200 are made by Saturation Permeameter and below $H = 200$ by the B of S. method.

Table 1-1: test by the Saturation Permeameter (Not reliable below $H = 1000$)

TABLE III

Curve for transformation ratio for standard steel for range $H = 50$ to 400

Method of Test

1. **Material:** Several rings were punched from a single sheet of standard sheet steel .014 in. From these punchings several rings were made of the same weight, and similarly wound for preliminary test. Two rings were selected having as nearly as possible the same magnetization curve.

2. Windings: The two selected rings were now wound for the differential test; the potential coils were wound next to the iron and were of about 500 turns of fine wire uniformly wound, each ring having the same number of turns. The magnetizing coil was made of a cable of twenty conductors, connected in series, with a tap at each joint. This scheme of winding permits a change of magnetizing value from any predetermined value to higher values in small and definite equal steps.

3. Scheme of wiring: The two magnetizing coils of the two rings were connected in series; the two potential coils were also connected in series. In all respects the scheme of wiring was the same as the usual scheme for tests on toroids. Two dial switches were provided for control of number of windings. One of the rings was used for measurement and the other for compensation. The potential coil of the compensating ring was provided with a supplementary potential coil of few turns and a fractionizing shunt for exact adjustment of the compensating interlinkage. (For wiring diagram, See Fig. 3-0.)

4. Test procedure for magnetization curve: The magnetization coils of the compensating ring and the test ring are tested alone according to the usual procedure. The galvanometer is calibrated to read 100 gausses per millimeter. Assuming that an error in reading the galvanometer cannot exceed half millimeter, it follows that the relative error does not exceed 50 gausses.

5. Test procedure for differential test: The galvanometer is calibrated to read a flux density of one gauss per millimeter of deflection. The dial switches of both rings are set at 10 each; the magnetizing current is adjusted to give $H = 50$, 100 or 200. On reversing the magnetizing current, there should be no deflection, that is, if the two rings are exactly alike; but as there is always a slight difference, a small deflection is produced in all cases, which can be eliminated by a careful adjustment of the supplementary coil and fractionizing shunt. The dial switch of the test coil is now set at No. 11. On reversing the current, a deflection is produced which represents the increment of flux density in the test ring. Other details of test procedure are too obvious to need explanation.

6. Limits of error: The relative error of any individual point in relation to the whole curve does not exceed 0.5 gauss (corresponding to half millimeter of deflection) and is probably much less for small deflection, which is capable of being read correctly to 1/5 of a millimeter. The whole curve may, however, be in error by any amount not exceeding 50 gausses.

In interpreting the curve, it is permissible to assume the curve to be straight enough for extrapolation, and yet the error in the indicated value of S may be as high as 50 gausses, even though the plotted curve were strictly a straight line.

Note: The original measurements were made in terms of H and apparent B; the true value of B was computed by making correction for space factor.

TABLE III-II

Curve for Incremental Reluctivity for Standard Steel for Range H = 300 to 1000 g

This test is similar to that of test table 3-1, except that the increment ΔH is in each case one-twentieth part of H. The magnetizing coil of the test ring was made up of two parts of 700 turns, and 35 turns; the first section alone produces the magnetizing force H_1, and the two sections produce the force H_2. The compensating ring has the magnetizing coil of 700 turns, which also gives the magnetizing force H_1. The potential coils are connected as in test 3-1, giving the value ΔB. Each ring is also equipped with a compensative bakelite ring (see table 4-1) which gives the result in terms of $\Delta \beta$ instead of ΔB. The values ρ', log ρ' and $\sqrt{\rho'}$ are obtained by computation.

TABLE IV

Magnetization Curve for Standard Steel

The ring used for this test is the same as the test ring in Table 3, Fig. 3. The ring was unwound, and rewound with heavier wire to obtain a magnetizing force of H = 1000. In order to eliminate space factor error a compensative ring of bakelite of the same size as the test ring, and wound with the same number of turns of same size wire, was used as a companion ring. The two rings were then treated as a single ring and wound with a common magnetizing coil. During test, the two potential coils of the test ring and the compensative ring are connected in opposition; this arrangement compensates for the entire spatial flux inside of the potential coil of the test ring, and therefore serves the double purpose (1) of eliminating the space factor error and (2) of deducting the spatial flux in the magnetic material. With this arrangement, the galvanometer deflections indicate directly the intrinsic flux density. In testing for saturation value, this method of compensation has the further advantage that the measurement of β is not affected by errors in measurement of the magnetizing current; the adjustment of the current need not be accurate; this permits rapidity of measurement and prevents excessive heating. Without this facility, measurement of saturation value in toroid rings would have been impracticable except in the case of permalloy and other similar material of low magnetic hardness. The following is the result of the test:

TEMPERATURE AFFECTS RADIO SIGNAL STRENGTH

That temperature influences the strength of radio signals is the conclusion reached by L. W. Austin and Miss Wymore of the Bureau of Standards, Department of Commerce. This work is a part of the program of the International Union of Scientific Radio Telegraphy, which was adopted at Brussels in 1922 and is now being carried on in the various countries belonging to the Union.

Two years ago, Dr. Austin described a decided increase in the signals received at Washington from the Radio Corporation transatlantic stations at Tuckerton and New Brunswick, N. J., during the passage of severe cold waves over the eastern states. Further study now indicates that whenever the temperature rises along the signal path there is a tendency for the signal to drop; and conversely, a falling temperature tends to produce a stronger signal, though these temperature effects are often masked by other unknown influences.

Experiments on the relations existing between meteorological phenomena and radio transmission require preferably at least fairly uniform meteorological conditions between the sending and receiving stations. For this reason, stations between 125 and 190 mi. distant were chosen for the experiments, rather than stations at great distances. On the other hand, stations much less than 125 mi. distant would probably not have shown the influence of weather changes to so marked an extent.

There seems to be no doubt that the temperature changes influence the waves which are reflected or refracted from the Kennelly-Heaviside layer, 60 mi. or more above the earth's surface rather than the waves which glide along the ground, since no marked change is observed in signal intensity due to long continued rain or drought, the presence of snow, or the presence or absence of frost in the ground.

ELECTRICITY USED TO RUSH FLOWERS

Turning a dark cellar into a bright solarium and growing tropical plants in greenhouses 5000 mi. north of their native habitat are realizations. These things have been done with the aid of electric light. In an experimental greenhouse in Yonkers, N. Y., all sorts of weird results have been obtained by running a traveling crane up and down all night over the glass roof, flooding electric light in varying intensities over beds of plants and flowers from the four corners of the earth. About 100,000 candle power made sweet peas bloom five weeks ahead of their daytime schedule. Oriental clover that requires two years to bloom under natural conditions blossomed in two months under 24 hours of daily light. Orchids were produced at will and brought to fullest flower on certain fixed schedules, thus presaging strange doings in the horticulture of the future by electric agents.

Abridgment of

An Investigation of Transmission-System Power Limits

BY C. A. NICKLE[1] and F. L. LAWTON[1]

Associate, A. I. E. E. Associate, A. I. E. E.

Synopsis.—*Results of theoretical analysis, verified by miniature-system tests of the power limits of transmission systems, are discussed, among the major conclusions being the following:*

The criterion for stability under all conditions is the steady-state power limit.

The charging kv-a. exercises marked detrimental effects on stability.

The characteristics of synchronous terminal apparatus are of great importance.

Improvements can be made by modifying present apparatus design.

Automatic voltage regulators, suitable exciters, and fast relays are essential.

The mercury-arc rectifier, as an adjunct in excitation circuits, shows real advantages.

INTRODUCTION

THE subject of transmission-system power limits and related problems is one of utmost importance in present and future projects, as emphasized by recent papers.[2]

The present paper deals with the results of careful theoretical analysis and calculations, verified by extensive miniature-system tests, of the power limits of transmission systems. Theoretical studies have been checked by tests on a miniature system equipped with synchronous apparatus, lines of variable constants, exciters, regulators, etc., and so chosen that 2300 volts and 180 kilowatts corresponded to 220,000 volts and 15,000 kw. on the actual system. The work covered was planned and directed by Messrs. R. E. Doherty and H. H. Dewey, and to a large extent outlined by them in a recent paper before the Institute.[3]

In addition to investigations relating to a basic knowledge of power limits of systems, attention has been focused on methods of improving their stability—in other words, increasing the power limits. In this connection, careful analysis has been made of special types of synchronous equipment, voltage-regulation schemes, induction generators, use of static condensers for the compensation of line inductive reactance, and many other devices. The work has been paralleled throughout by studies of actual projects.

In the computation of power limits, a thorough knowledge of the theory of synchronous machines is essential. It can be shown that, for all practical purposes, it is unimportant whether salient-pole or cylindrical-rotor theory be used in the calculation of all quantities but angular relationships. As steady-state power-limit studies made by the authors have not involved angular relationships, the use of either theory is justified. In transient problems, however, angular relationships are of fundamental importance and, hence, the appropriate theory must be used.

A large amount of work has also been done on the power-angle characteristics of synchronous machines. Papers dealing with these studies, and synchronous-machine theory, will, it is hoped, be presented before the Institute in the near future.

Among the important conclusions reached as a result of the investigations made by the authors, and other interested engineers of the General Electric Company, may be mentioned:

1. Too great importance must not be attached to the transmission line as it is but one link in the circuit; the characteristics of terminal apparatus, such as synchronous machines, and methods of voltage regulation are of equal, if not greater, importance.

2. The only feature in which the stability of high-tension long-distance transmission and high-tension cable systems differs from that of any other type is in the limitation of the excitation of synchronous apparatus due to the charging kv-a. of the lines.

3. For slowly-applied loads, automatic voltage regulators and suitable exciters permit stable operation up to the same limit which can be obtained with manual control.

4. The problem of obtaining greater power limits offers two avenues of approach:

    (*a*) Modification of the characteristics of existing synchronous apparatus and transmission lines.

    (*b*) The development of new methods of voltage regulation.

5. Extensive miniature-system tests indicate that, no matter how fast load is applied, under similar conditions of excitation or voltage the power limit is always the same as the steady-state limit. In view of these results and experience, it appears that the

fundamental criterion of power-system stability is the final steady-state power limit.

6. Adequate speed of relaying is the vital factor in the maintenance of stability during system short circuits.

7. Reliable methods of calculation of system power limits, for steady-state conditions, are available. For the more complicated networks, a-c. miniature systems give excellent results.

8. At present there are no satisfactory methods of computing system power limits, under transient conditions, for any but the simplest cases. However, it is possible to study completely all transients ensuing from disturbances which do not result in instability, by means of the electromechanical analyzer.

Methods of Calculation

It has been indicated that reliable methods of determining system steady-state power limits are now available. In general, it has been found that the method of calculation adopted by the authors gives results of good engineering accuracy, as shown by the computed and test values given in this paper. Furthermore, these results agree very well with those secured by independent investigators using other schemes of analysis.

Calculations of system steady-state power limits are comparatively easy for simple systems comprising, say, one generating station, a line or two, and one receiving station. Where several branches are involved, analysis becomes more difficult; partial solutions by graphical methods are combined to give a complete solution. When the system under consideration comprises many branches, computation by these graphical methods becomes practically impossible and resort must be had to analysis by miniature a-c. systems.[4] Steady-state stability problems can be solved with the aid of miniature a-c. systems of the same order of size as the d-c. short-circuit calculating table, which has been of such invaluable aid.

For the study of system transients arising from dropping a line, suddenly adding a load, etc., there is no practical scheme of analysis available for any but the simplest cases. The unwieldiness of the step-by-step method[5] increases very rapidly with the number of elements in the system, and it soon becomes impossible of application. However, by using the equivalent-circuit idea,[6] it is possible to study the electromechanical transients in any system, no matter how complicated, for loads below the power limit; that is, where the differential equations for the system are linear.

Description of Miniature System and Methods of Testing

When the investigation was commenced, it was realized that means should be available for verifying promising leads developed in analytical studies, and establishing the reliability of methods of calculation. Inasmuch as it was not feasible to use an actual system for this work, a miniature system of sufficient capacity to give reliable test information was set up in the factory. The equipment included several 225-kv-a. synchronous motors with direct-connected d-c. generators, units for setting up any type of line, exciters, standard vibrating-contact regulators, etc. By using the d-c. generator of a set as a motor supplied from the shop bus, and the corresponding unit of another set as a separately-excited generator supplying a water-rheostat load, it was possible to study systems comprising four synchronous units. The use of resistance loads prevented any possibility of hunting due to a feed back on the shop bus. For simulating an infinite generator, a 10,000-kv-a. alternator was available.

To correlate results obtained by miniature test with corresponding values for the actual system, it should be borne in mind that the miniature system was designed so that a voltage of 2300 corresponded to 220 kv. on an actual system; similarly, 180 kw. was equivalent to 150,000 kw.

Steady-State Studies

It is evident that any analysis of transmission-system power limits falls into two major divisions—one dealing with the limits obtaining for slowly-applied loads, as in steady-state operation, and the other with the limits for transient-state, suddenly-applied loads. Accordingly, the treatment of the subject in this paper follows more or less the above division.

Influence of Circuit Elements on Power Limits. The first system studied was a simple, two-machine system consisting of two 225-kv-a. units connected directly together, electrically. The machines were synchronized, the excitations adjusted to the desired values and maintained constant at those values, together with system frequency, as the load was slowly increased by increasing the d-c. generator excitation.

The next step consisted of the introduction of lines of various constants, proportional to different lengths of the actual 220-kv. transmission line. By computing the power-voltage curves for a system comprising an alternator, a line, and a synchronous motor, it was possible to determine the effect of the added impedance on the power limit. No effort was made to include the capacity susceptance of the actual line in the first analysis; this was done later. The constants of these lines, designated *L-R* lines, were as follows:

125-mi. *L-R* line $z_L = 1.27 + j\ 9.25$ ohms
250-mi. *L-R* line $z_L = 2.54 + j\ 18.5$ ohms
500-mi. *L-R* line $z_L = 5.09 + j\ 37.0$ ohms

A comprehensive idea of the relative effect of the various circuit elements on power limits can be gained by a study of Table I, which summarizes representative results for the different systems discussed.

The values given in Table I are self-explanatory. They indicate, among other things:

1. The importance of voltage regulators if the maximum possible operating capacity is desired.
2. That transmission-line impedance plays a large part in reducing the maximum power limit but that the synchronous-apparatus characteristics are equally important.
3. That transmission-line capacity susceptance reduces the power limit considerably.

Sufficient has been said in the preceding discussion to indicate that a system with a number of machines operating in multiple should have a higher power limit than the simple straightaway transmission by virtue of the fact that the generating bus, or receiver bus, tends to become an infinite bus, a fact verified by investigation. Table II illustrates the effect of adding multiple generators and summarizes the power limits for a number of systems.

Use of Voltage Regulators. A brief survey of the comparative power limits given in Table I will indicate the advantage of operating a system at normal terminal voltage rather than normal excitations. It is not, of course, intended to infer that systems are so operated but merely to establish bench-marks to indicate the advantage, with respect to power limit or stability, of constant-voltage operation. As noted, the ratio of the normal-regulator power limit to the normal-excitation power limit varies from 2.5 to about 1.6, depending on the relative impedance of the circuits.

In view of the importance of maintaining those excitations which correspond to normal terminal voltage at the load being carried, it seems well to discuss at this point the mechanism of the operation by which the regulator maintains constant terminal voltage. Referring to Fig. 1, a number of power-voltage curves, with excitation as parameters, are shown. Suppose the system to be operating with excitation (i_4) and load (P_2). An increase in load of about 20 per cent will cause pull-out at that power at which $\frac{dP}{dE} = 0$. To carry a load greater than that causing pull-out at excitation (i_4), it is necessary to increase the excitation to, say, (i_6). In this case pull-out will occur at a load (P_3).

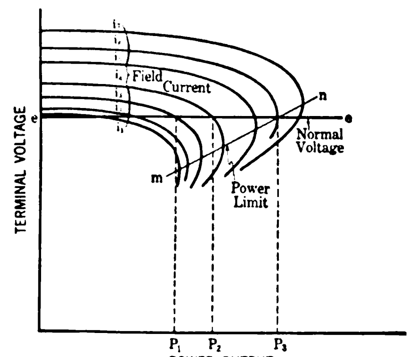

FIG. 1—TYPICAL CONSTANT-EXCITATION POWER-VOLTAGE CURVES

While it is possible to manually adjust the excitations for slowly-increasing loads, this is not feasible where rapid load additions may occur. Resort must accordingly be made to some automatic device which will rapidly adjust the excitation to the value corresponding to the actual load and the desired operating voltage. Such a device is the vibrating-contact type voltage regulator. It will be interesting to examine its operation.

As is well known, the voltage regulator is designed to maintain constant voltage at some point on a system—in this case, the supply and receiver busses. This is accomplished by increasing the excitation of the proper machine when the voltage at the regulated bus drops or vice versa. However, at any constant load, power factor and voltage, there is a definite excitation required, namely, that given by the intersection of the co-

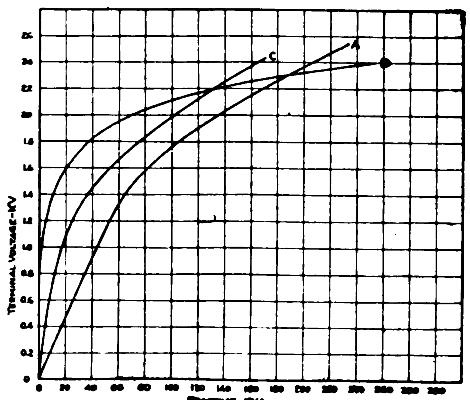

FIG. 2—VOLTAGE-REACTIVE KV-A. CHARACTERISTIC CURVES FOR VARIOUS REACTORS

Curve A—184 kv-a. unsaturated reactor
" B—184 " saturated reactor
" C—225 " synchronous condenser with 1.0 ampere field current

ordinates corresponding to power and voltage. In other words, the voltage regulator adjusts conditions by causing a transfer of operation from one constant-excitation (power-voltage) curve to another. It follows, then, that pull-out will take place at the intersection of the straight line representing the constant operating voltage with the locus of pull-out points, *i. e.*, power (P_3) and voltage (e), corresponding to excitation (i_6). This is the maximum power which can be delivered by the system at voltage (e). With imperfectly adjusted regulators, however, pull-out will take place at some power less than (P_3).

It must be borne in mind that system operation with voltage regulators consists of nothing more than a succession of steady-states, each with some particular constant value of excitation. If, for any reason, the regulators are unable to adjust conditions to those corresponding to stable operation, at any load, pull-out will take place along the power-voltage curve corresponding to the particular excitations then obtaining.

The preceding discussion will emphasize the vital necessity for voltage regulators on systems which it is desired to operate at loads close to the maximum power at the system voltage. This point has been demonstrated by actual experience on systems.

Influence of Machine Nominal Voltages on System Stability. Analysis of the preceding investigations led to the conclusion that system stability could be improved by increasing the machine nominal voltages for any particular terminal voltage. Two simple methods of accomplishing this were available, namely, the use of static shunt reactors and synchronous reactors (condensers). Accordingly, the use of such devices was investigated and a number of tests made.

The increase in power obtained by means of a shunt reactor is due to the greater excitation required to maintain a given terminal voltage for given power conditions. This increased excitation could be obtained more economically by lengthening the air-gap of the machine.

Similar results were obtained using an under-excited synchronous condenser in place of the shunt reactor. The current taken by a synchronous condenser is the difference between the terminal voltage and the nominal voltage divided by the synchronous reactance. When the nominal voltage is zero, the current is just the terminal voltage divided by the synchronous reactance, and the current-voltage curve is identical with that of a static reactor.

Having shown the effect of reactors, either static or synchronous, in increasing machine nominal voltage, studies of systems with lines were undertaken. The static reactors considered were of two types:

a. Unsaturated iron-core reactor
b. Saturated iron-core reactor

In Fig. 2, characteristic curves for the actual reactors used are compared with a corresponding curve for the synchronous condenser.

The advantage of using a saturated iron-core reactor[7] lies in the fact that the rate of change of reactive kv-a. consumed with respect to terminal voltage is much greater than for the ordinary non-saturated reactor. In other words, at normal voltage, the kv-a. consumed by the two types of reactor is the same, but at a lower terminal voltage, the kv-a. taken by the saturated reactor is much less. Therefore, any disturbance in the system producing a voltage decrease will cause a reduction in the armature reaction of the synchronous equipment, due to the reactive kv-a. taken by the reactor, thus making an increase in machine excitation available for maintaining stability.

With an appreciation of the effect of shunt reactors on system power limits, it is quite easy to see why the line capacity susceptance should reduce the power limit.

Consider a system which simulates an actual 250-mi. straightaway system in which the actual line is replaced by the "nominal π" line. The capacity susceptance is, so far as its effect on the machine nominal voltages is concerned, simply a *negative* shunt reactance of about 70 ohms, reducing the required excitation for a given terminal voltage.

In this connection, it is interesting to consider the effect of adding multiple lines between generating and receiving equipment of a given kv-a. rating. Due to

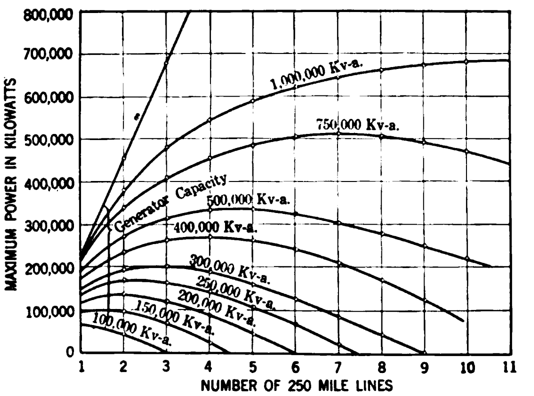

FIG. 3—MAXIMUM POWER WHICH CAN BE TRANSMITTED 250 MILES AT 220,000 VOLTS, SHOWN AS A FUNCTION OF THE CAPACITY OF SYNCHRONOUS APPARATUS, AND THE NUMBER OF TRANSMISSION CIRCUITS

the increase of charging kv-a. with numbers of lines, a point is soon reached where the decrease of machine excitations more than counterbalances the effective decrease in line reactance. When the number of parallel lines is increased beyond this point, a reduction in the power limit occurs. Fig. 3 illustrates this condition.

It is evident that shunt reactors may be used to compensate for the effect of the leading kv-a. taken by the line capacity susceptance, and thus improve the power limit. Actual studies of reactors and synchronous condensers on large projects indicate that the reactors may be the more advantageous, on the score of economy. As previously pointed out, the same result can be gained by lengthening the air-gap of the synchronous apparatus.

"Saturated" Machines. It should be evident from the preceding discussion that *any measure by which the field current can be increased with the same terminal voltage will improve the stability.* Several methods of accomplishing this have been mentioned under the head of "Influence of Machine Nominal Voltages on System Stability." In addition to methods previously discussed, there is another—that is, increasing the degree of saturation of the poles.

Consider the saturation curves of two synchronous machines as shown in Fig. 4, one for a "normal" machine with operatng range on the saturation curve somewhat below the knee, the other with normal voltage well above the knee. Furthermore, the machines will be of identical design except in so far as the cross-sectional area of the poles is concerned.

If the two machines be operated separately as generators with such field currents that normal terminal voltage occurs at no load, identical power increments on each will not cause the same lowering of the terminal voltage. In other words, *the saturated machine is stiffer.*

Such tests as were made indicate that the benefits obtained by the use of synchronous generators and motors with saturated poles are of the same order as could be obtained by lengthening the air-gap.

Use of Induction Generators on Transmission Systems. Induction generators have been suggested from time to time for use in connection with long transmission lines, but they have never come into practical use. During the course of the present investigation it was felt that there were certain merits in such use which should be carefully investigated. As known now, the power which can be transmitted over a line between two synchronous machines is limited by the phase relationships of the system. With the induction generator, however, the power delivered from the prime-mover shaft to the generator terminals depends upon the difference in speed of the prime mover and the terminal-voltage vector. With a prime mover and a rotor capable of transmitting any desired power from the prime-mover shaft to the stator circuit, the power limit will be dependent upon the angle between the rotor of the re-

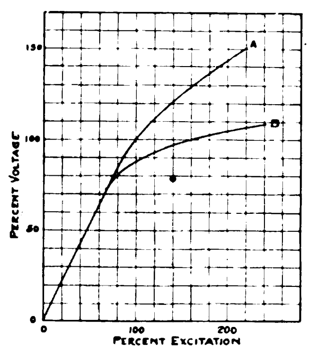

FIG. 4—OPEN-CIRCUIT CHARACTERISTIC CURVES
Curve A—Normal generator
Curve B—Saturated generator

ceiver-end motor and the air-gap flux of the generator. That is, the power limit of synchronous-to-synchronous transmission is a function of the angle between the machine rotors but with induction-synchronous transmission is dependent upon the angle between induction generator air-gap flux and synchronous motor rotor.

Although economic studies may indicate a possible margin in favor of the induction generators, there is practically no advantage to be gained by their use, so far as stability is concerned.

"Loaded" Transmission Systems. In recent years much attention has been given to the possibility of increasing the stability of power systems by the use of synchronous condensers at intermediate points.[8] Investigations made by the authors indicate that greater gains have been ascribed to such use of synchronous condensers[9] than is actually the case.

The addition of a synchronous condenser of the same rating as the terminal apparatus to the simple 500-mile *L-R* straightaway system increases the power limit at normal voltage from 110 kw. to 150 kw. or about 36 per cent. It must be remembered, however, that on actual systems, the synchronous condensers at loading points would ordinarily have a much smaller capacity than the terminal apparatus. Consequently, the percentage increase in power limit will be much less. Moreover, actual systems have lines with distributed capacitance which tends to accomplish the same object as the loading condenser. In other words, to secure any appreciable increase in maximum power of actual systems, the condenser used for loading must have a kv-a. capacity much higher than indicated by early investigations[10].

Like most problems of this type, the advantages of loading condensers, for any particular project, cannot be definitely stated without a careful economic study.

"Resistance" Loading of Transmission Systems. All the systems discussed so far have had synchronous motor loads—in other words, typical shaft loads, which have constant kilowatt and variable reactive kilovolt-ampere consumption; that is, the power is independent of the voltage. No reference has been made to high power-factor admittance loads, such as lighting, industrial heating, etc. It will, therefore, be interesting to turn attention for a few moments to the question of such loads—"resistance" loads—for long transmission systems.

Consider two synchronous machines tied together through an impedance. It is well known that the limit of stability occurs at the point at which $\frac{dP}{dE} = 0$, a fact verified many times by test. The criterion for maximum power, $\frac{dP}{dE} = 0$, holds only where power is the independent variable, as in shaft loads. Suppose, however, that one of the synchronous machines in this combination is replaced by a dead impedance load. Then, instability will *not* occur at the point where $\frac{dP}{dE} = 0$, nor at any other point, since for a dead load there is nothing with which the generator can fall out of step. There will, however, be a *maximum power* point for constant excitation on the generator. If voltage is maintained at the load by a synchronous condenser, it can be shown that instability will occur where $\frac{dR}{dE} = 0$, instead of $\frac{dP}{dE} = 0$, where the resistance (R) of the dead load is the independent variable.

The importance of choosing the proper criterion can be better appreciated if it is understood that a pure resistance load with a synchronous condenser for voltage regulation is equivalent to an infinite bus, as far as maximum power under steady-state conditions is concerned. This statement is true only when there is no other load on the system. To emphasize the importance of choosing the proper criterion, a system comprising both resistance and shaft loads may be cited.

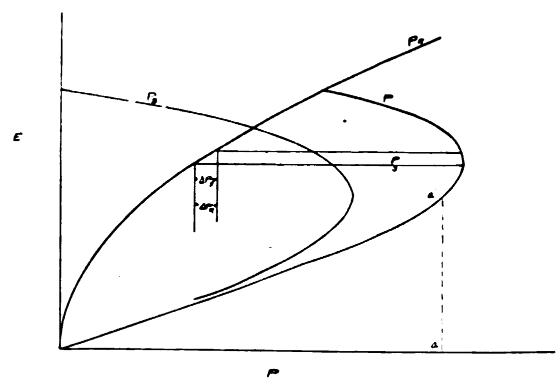

FIG. 5—TYPICAL POWER-VOLTAGE CHARACTERISTICS FOR SYSTEM WITH COMPOSITE SHAFT AND RESISTANCE LOAD

In such a case, consider what happens when the shaft load is increased. Any increment of shaft load results in a decrease of terminal voltage and, hence, a decrease in power consumed by the resistance load. A set of typical power-voltage characteristics of a system with both shaft and resistance load is shown in Fig. 5. Curve (P) represents the variation of total power with voltage, (P_R) the variation of resistance power with voltage, and (P_S) the variation of shaft power with voltage. It is evident from the figure that the slope of the curve of total power becomes infinite—that is, $\frac{dP}{dE} = 0$—at that point where an increase of shaft power is exactly equal to the resultant decrease in resistance power. However, *the system is still stable,* inasmuch as the slope of the curve of shaft power has not yet become infinite, and (P_S) *is*

the independent variable. Breakdown occurs where

$$\frac{d\,P}{d\,E} = 0,$$

and the total power is as shown by the ordinate $(a\,a')$. In other words, a system with such a composite load may be stable even though operation is on the under side of the total power-voltage curve.

Compensation of Transmission-Line Inductive Reactance. Preceding discussion has shown the effect of the reactance of long transmission lines in limiting the amount of power which can be transmitted with stable operation. It is, then, apparent that any means by which this effect could be economically reduced would be advantageous. It is possible to reduce the line reactance by use of special line construction[10]. However, the decreased line reactance is gained at the expense of an increase in charging kv-a., which may partially offset or even more than offset the advantage gained.

However, by introducing series static condensers into the line[11], it is possible to effectively neutralize or compensate for the effect of line inductive reactance without any increase in charging kv-a. There are certain difficulties attendent upon such use of static condensers, as protection from excess voltages during short circuit. Careful investigations show the feasibility of series static condensers for this service hinges almost entirely on over-all economy.

Influence of Methods of Voltage Regulations on Stability. Careful analysis of the effect of various circuit elements, and special types of apparatus, on transmission-system stability, as discussed elsewhere in this paper, will indicate that the real criterion of stability is the inherent slope of the power-voltage characteristic. In other words, instability occurs when the slope of the power-voltage curve is such that

$\frac{d\,P}{d\,E} = 0$, for shaft loads. How can this occur in a

power system, the synchronous machines of which are provided with automatic voltage regulators?

As pointed out under "Use of Voltage Regulators," the regulator is merely a device for shifting the system from one constant-excitation condition to another, as dictated by the terminal voltage. Referring to Fig. 1, voltage is maintained by the regulator functioning in such a way that the system operates along the line (ee) by passing from one constant-excitation state to another. However, and this is the important point, the inherent stability of the system is not that indicated by the slope of the line (ee)—*i. e.*, $\frac{d\,E}{d\,P} = 0$ — but by the slope of some constant-excitation curve. It may be anyone of a number as shown, but it is always some one of the family of curves. It is in just this respect that regulated machines do not have the characteristic of an infinite bus with $\frac{d\,E}{d\,P} = 0$, the ideal type of voltage regulation.

In this connection, it will be of interest to examine the phenomena accompanying an increase of load on a piece of synchronous apparatus in a transmission system. Such an increase in load will result in a decrease in terminal voltage with a given excitation.

Now the voltage regulator is not responsive to the rate of change of voltage, but only to a value of voltage —the function itself; hence, it increases the excitation in the degree necessary to compensate for the increased armature reaction due to load only after the lapse of an appreciable time. That is, the field excitation is increased only after the voltage has dropped. Such investigations as made by the authors do no indicate that any appreciable gain in power limit can be secured by reducing the time constant of the excitation system below that of normal equipment. Compensation for increased load, and, hence, armature reaction, always lags behind the cause. This is important during transients and especially near the point of intersection of (ee) and (mn)—the point of pull-out. It is the reason why a system with regulated generating stations cannot be considered as having infinite supply busses and hence a power limit equal to that of the line itself.

Consider what happens when load is added to a d-c. generator provided with a compensating field winding. Simultaneously with the increase in armature reaction, a magnetomotive force is set up in opposition to it. Depending on the size of the compensating field, the effect of increased load may be entirely counterbalanced or compensated for—even over-compensated. A similar case is that of a circuit in which the inductive reactance is exactly balanced by an equal series capacitive reactance. What happens when the circuit load is increased? The voltage drops across both inductive and capacitive reactances increase simultaneously, but being of opposite phase, effectively neutralize each other. With respect to the terminals, there is no reactance drop.

Applying the principle enunciated above—*i. e.*, the effective neutralization of the cause by making the effect take place simultaneously—to synchronous equipment, the great importance of it can be seen. The machines in effect would have infinite capacity, limited only by heating and mechanical considerations. To realize the significance of this, refer to Table I and related discussion, where it is pointed out that the power limit of a 250-mi. miniature *L-R* line by itself is

10. *Output and Regulation of Long-Distance Lines*, Percy Thomas, TRANS. A. I. E. E., Vol. 28, 1909, p. 615.

11. Discussion by T. A. E. Belt on "*Present State of Transmission and Distribution Developments*," JOUR. A. I. E. E., Vol. 44 October, 1925, p. 1153.

283 kw., but with normal machines, only 168. kw. That is, the synchronous reactance of the machines reduces the power limit about 41 per cent. In actual systems, the effect of the generating and receiving equipment might even increase this value to 50 per cent.

It is evident that if some device can be applied to synchronous apparatus which will prevent a reduction of the net ampere turns tending to force flux through the magnetic circuit, such a device will effectively decrease the effect of armature reaction which is so detrimental to the stability and power limits of long transmission systems. That is, as load builds up, the armature reaction builds up, but simultaneously and due to exactly the same causes, the field ampere-turns must build up with the right magnitude and space phase to compensate for the armature reaction. *The perfect simultaneity of cause and effect effectively neutralizes armature reaction.*

Of course, to obtain the ideal in voltage regulation, the inherent reactance of synchronous machines must also be neutralized—as by the use of series static condensers of suitable capacity—in the same way that the effect of line reactance may be overcome.

It is apparent that it is somewhat difficult to completely accomplish what has been outlined above—for the effective compensation of armature reaction necessitates the application of field ampere-turns in the proper space phase and varying in magnitude and time with the armature reaction. It was realized, however, that any device which would increase the excitation in exact proportion to the armature reaction—or line current—and in perfect simultaneity with it, should be of considerable advantage.

Accordingly, a number of devices and methods for accomplishing this object were carefully investigated. Finally, it was decided that ordinary mercury-arc rectifiers used as adjuncts in the otherwise normal excitation circuits of synchronous apparatus appeared to offer the greatest promise.

The use of mercury-arc rectifiers has shown, in factory tests, that a very appreciable gain in stability and power limits can be secured. While practical application on power systems has not yet been made, it is confidently believed that at least a 50 per cent reduction in effective armature reaction can be secured. Moreover, a real scheme of voltage regulation, effective under steady and transient conditions, is for the first time made available.

Transient Studies

When the question of the stability of power-transmission systems recently came to the fore, it was thought that the worst condition of operation likely to be faced would be that obtaining during transient conditions. Such a transient state might arise from:

a. Sudden loss of a generating station

b. Sudden addition of load

c. Sudden loss of one or more multiple transmission lines

d. Major system short circuits

In fact, it was quite generally expected that the power limit for such transient conditions would be less than the steady-state pull-out power.

However, very complete analytical studies, verified by thorough tests on the miniature system used for the steady-state power-limit investigations previously discussed, have largely dispelled the doubts of successful operation of extensive power systems under heavy load transients. Briefly, the following important conclusions have been reached from the evidence furnished by analysis, miniature-system tests, and field experience.

1. The power limit of a system, when load is suddenly applied to some element in that system, is the same as the pull-out power for slowly-applied loads, provided conditions of excitation and voltage are the same for the two cases. Certain transitory phenomena, discussed later, so affect system stability that *the fundamental criterion of stability appears to be the steady-state power limit.*

2. Power oscillations during a transient-state induced by the sudden application of load will not be excessive with units of comparable rating at the various points on the system. With an infinite generating unit, or an extremely large system interconnected with a relatively small one, the power "overshoot" may approach 100 per cent of the load increment.

3. Maintenance of stability during short circuits is mainly a matter of adequate relaying as duration of the short circuit is probably the most important single factor entering the problem.

During the existence of a transient state caused by a sudden change of load or a short circuit, a number of factors come into play which do not appear in steady state operation. Among others, there are the kinetic energy of machines, the time element of electromagnetic circuits, as in excitation systems, and the load-time characteristic of prime-mover governors. For these reasons, the calculation of transient problems is much more involved than the computation of steady-state stability. However, rigorous mathematical methods and step-by-step analysis[5] can be applied to the simplest cases. The analysis of systems of any degree of complexity becomes almost hopelessly involved so that resort must be had to the equivalent-circuit idea[6], which is extremely useful for the study of transients involving loads below the steady-state power limit.

Effect of Suddenly Applied Loads. Inasmuch as the basic purpose of the transient studies undertaken by the authors and other interested engineers was the determination of the relation between steady-state and transient stability, and the factor affecting the latter, the miniature system previously described was utilized. It was possible to simulate the sudden loss of a generating station by opening the oil switch tying a generating unit to the system; the sudden addition of shaft load by

closing a switch throwing a water-rheostat load on the d-c. generator coupled to a synchronous motor at the receiver end of a system; the sudden addition of "resistance" load by switching a dead resistance load directly onto the system; and the sudden loss of one or more multiple transmission lines by opening the oil switch in one of two 250-mi. *L-R* lines connecting a 225-kv-a. generator to a synchronous motor of identical rating.

The steady-state power limit of any particular system studied was first obtained for various constant-voltage or constant-excitation conditions. Then, by means of repeated trials, it was possible to determine how much load could be suddenly added to the system without causing loss of synchronism,—instability. The results were tabulated for the various cases and, as mentioned, on analysis revealed the important fact that the power limit for transient state was essentially the same as that for steady state, under the same conditions of excitation or voltage.

It will readily be apparent from what has been said that any time delay in the various elements making up a system would play an important part in transient stability. There are two such elements:

1. The electromagnetic circuits
2. The prime-mover governors

As the first is quite fully discussed later, only the second will be considered here. Inasmuch as governors are relatively sluggish in action, it may be several seconds after a disturbance occurs before the governors of a system assume their new positions. Consequently, in analysis of what happens during the first moment or two, constant flow (of water, or steam) is commonly assumed.

Short Circuits. Load transients apparently do not decrease the power limit of a system but the transient conditions obtaining during a major system short circuit radically affect stability. Not only do the inertias of machines and the time elements of governors and excitation systems come into play, but also the isolating effect of the short circuit. That is, no power flow can take place past the point of short circuit in the phases affected. For this reason, if the fault is not quickly cleared, a three-phase short circuit is likely to result in instability. Single-phase short circuits, whether line-to-line or line-to-neutral, are not so serious, inasmuch as partial flow of power is possible.

Brief consideration of what takes place in a system during a short-circuit disturbance may be illuminating. Assume a straightaway transmission with a single-phase line-to-line short circuit at the midpoint.

Just prior to the occurrence of the short circuit, the machine rotors will have a definite space-phase relationship fixed by the constants of the system, the load and the voltage. The instant the disturbance occurs the transfer of power between the machines changes, ceasing entirely in the faulty phase, and the rotors commence to assume a new relative position in space, depending on load and voltage conditions prior to the short circuit, the power flow, and the governor characteristics. Consider the generator. If the torque exerted by the system remains at the same value as previously, the net effect on the generator during the first instant will be zero. However, as the net flux is reduced and, hence, the voltage, this torque is likewise reduced and the machine accelerates, assuming no action on the part of the governor. Should the governor act, this acceleration will be reduced. The rate of change of net flux will be rapid in the first few instants, gradually decreasing with increasing time. This, of course, assumes no action on the part of the regulator tending to change the field ampere-turn loading. Should the torque imposed by short-circuit conditions be initially less than the load torque, the acceleration of the generator will, necessarily, be greater. It is evident, then, that the speed, the space-phase relationship of the generator relative to the initial position, and the magnitude of the net flux, (hence, terminal voltage) are functions of the duration of the short circuit.

Inasmuch as similar conditions hold for the receiver-end synchronous apparatus, it is apparent that *the essential factor for maintenance of system stability during short-circuit disturbances is adequately fast relaying.* Experience with actual systems has amply justified this statement.

Experience on existing systems, tests and conservative calculations indicate that major system short circuits are the severest type of transient. Only by very fast relaying can stability be maintained for powers near the steady-state power limit.

Effect of the Excitation-System Time Element on Transient Stability. In the discussion of system stability under suddenly applied loads, it has been said that certain factors so strengthen or stiffen the system that it is inherently stable for any load up to the steady-state power limit. What are these factors?

Undoubtedly, the most important element in the *temporary stiffening* of a system during a disturbance is the *field transient.* Due to the inherent relationship between field and armature circuits, the magnetic flux linked with an alternator field cannot change in the first moment following the sudden addition of load.[12] The increased armature current induces a field m. m. f. tending to sustain a constant flux linkage. If there is no automatic device increasing the exciter voltage, the flux will gradually die down to a new steady-state condition. However, and this is the important point, *during the transient, the machine reactance is less than the synchronous reactance.* Initially, following the sudden application of load or short circuit, the transient reactance[13] is effective, and this gradually increases

12. "*A Simplified Method of Analyzing Short-Circuit Problems,*" by R. E. Doherty, TRANS. A. I. E. E., Vol. 42, 1923, p. 841.

13. The transient reactance includes both armature and field leakage reactance.

to the steady-state synchronous value. Furthermore, the inherent stiffening of the system enables the regulator to act, causing the exciter to build up. Briefly, it is a race between the rate at which the system assumes the new load and the rate at which the excitation can build up. Now, the period of oscillation of a system is of the order of one second, and, hence, the first power peak occurs in a half-second. The *field transient*, or the transient reactance, stiffens the system sufficiently to meet this condition. By the time the power peak occurs again, the excitation system has

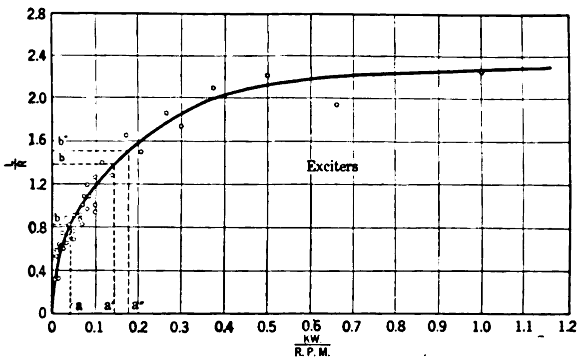

Fig. 6—Curve Indicating the Relation between the Time Constant and the Speed and Rating of Exciters

had considerable time in which to build up. In this respect, it will be interesting to note the relationship of the time constant $\left(\frac{L}{R}\right)$ to the volume of the exciter. Values for a large number of exciters, of different types and ratings, have been plotted in Fig. 6. In this case, the measure of volume used has been kilowatt per rev. per min., as this represents volume, for given current and magnetic densities. The actual exciters used in the experimental investigations are indicated by the points (ba), $(b'a')$, and $(b''a'')$.

It will be apparent that any scheme by which the resistance of the excitation circuit—that is, alternator field and exciter armature—can be reduced will tend to maintain constant flux linkages and so give the exciter a chance to build up. One method of accomplishing this would be the introduction of a *negative* resistance in the field circuit. A series exciter does function as a negative resistance. Its use in such a case has already been described.[3]

Neither the voltage regulator nor the series exciter, however, accomplish the primary object of the ideal regulation scheme—*i. e.*, the effective neutralization of armature reaction at the time it occurs. As previously pointed out, the mercury-arc rectifier, as an adjunct in excitation systems, does accomplish, to a large degree, this purpose, and in so doing, very materially stiffens any system so equipped, both in transient and steady states.

The inherent field transient so stiffens the average system that ordinary regulators and exciters are sufficiently responsive to maintain stability under heavy load transients. Mercury-arc rectifiers, or other devices accomplishing the same purpose, appear to be the most effective of all regulation schemes in reducing the effect of transients.

Conclusions

The preceding discussion has made it evident that the problem of stability is not confined to long-distance high-tension transmission lines, where economical considerations require operation close to the power limit. With the growth of the nation's power systems into widespread interconnected networks, and the consequent transmission of larger and larger blocks of power over short interstation tie lines, the problem of stability becomes vitally important, inasmuch as such short tie lines, on which depends reliability of service, may be operated too close to the power limit, with danger of instability.

In general, the investigations discussed have been most gratifying because they have indicated in what direction engineers interested in the design and operation of power systems should look for improvement. Furthermore, they have indicated that the real advances in obtaining additional stability lie in the application of certain types of apparatus—namely, devices for voltage regulation which fulfill the conditions of the ideal voltage-regulation scheme—*i. e.*, $\frac{dE}{dP} = 0$. Improvement may be effected by changes in design of present synchronous apparatus—such as lengthening the air-gap or operating the pole structures at high magnetic densities.

To summarize, then, the following important conclusions have been reached from the studies undertaken by the authors:

1. The characteristics of synchronous terminal apparatus are of great importance in their effect on power-system stability. In fact, they may be of greater importance than the transmission-line characteristics.

2. Automatic voltage regulators and suitable exciters are essential to obtain, under all conditions, the same power limit as could be obtained with manual control and slowly applied loads.

3. The charging kv-a. of long transmission lines and extensive cable networks exercises more of a detrimental effect on stability than has been hitherto appreciated.

4. Improvements in system stability can be readily made by modifications of present designs of apparatus. Investigations indicate that real advances in stability come from the adoption of methods of voltage regulation having inherent characteristics close to those of the

TABLE III
POWER LIMITS FOR SYSTEMS WITH SHUNT REACTORS

* The saturated reactor has a reactance of 29.2 ohms at 2300 volts.

ideal—*i. e.*, $\frac{dE}{dP} = 0$. One method studied—the mercury-arc rectifier as an adjunct in the excitation circuits of synchronous equipment in shop tests—showed real advantages.

5. The criterion of stability under all methods of load application appears to be the steady-state power limit.

6. To ensure stability during short-circuit disturbances, a well-designed and adequately fast relaying system is essential.

7. Results of good engineering accuracy can be obtained in the computation of system steady-state power limits by the application of available methods of calculation, although in the more complicated cases resort must be had to solution by the a-c. miniature system.

Discussion at Midwinter Convention

PAPERS ON TRANSMISSION STABILITY

(Nickle and Lawton, Clarke[1], Wilkins[2], Evans and Wagner[3])

New York, N. Y., February 8, 1926

R. D. Evans: Miss Clarke's paper dealing with the use of equivalent circuits for analyzing static stability, is of very considerable interest. Probably the most important contribution in the paper is the method of using an equivalent circuit to obtain the angle between generator and motor for maximum power. I believe this general method will find extensive use.

In carrying out the calculations, Miss Clarke replaces a complicated network with shunt admittances, by an equivalent network of a single series impedance, but with equivalent supply and receiver voltages. Sometime ago we had occasion to solve a transmission network in which many of the branches involved a long transmission line, and this led to a somewhat similar method of calculation. It is not convenient to go into the mathematical analysis at this time, but in the written discussion, we will submit an alternative proof of the method of using equivalent networks and equivalent voltages, which method is based on the use of general circuit constants and is of very simple form. I might say that some of the formulas used by Miss Clarke have been independently derived by us and that, for example, the transformation of the general network to the equivalent pi and vice versa, will appear in the revision of the "Electrical Characteristics of Transmission Circuits" by William Nesbit, which is now in press.

On the middle of the first page, Miss Clarke states that she takes the characteristics of synchronous machines into account by assuming a definite value of synchronous impedance and a definite value of excitation voltage. These assumptions are used to determine the static stability limit. These assumptions apply when the excitation is fixed but do not apply when the excitation varies under the control of automatic voltage regulator.

The determination of the proper method of representing synchronous machines for the calculation of static limits is beyond the scope of Miss Clarke's paper, but since it affects the static limit, it seems pertinent to comment upon this phase of the problem. The methods described by Miss Clarke are not applicable to the determination of the effects of voltage regulators since they do not permit the analysis of the time variation in excitation and of rotor movement. In the paper by Evans and Wagner, it is pointed out that the use of automatic regulators will actually increase the static limit over the value obtainable under

1. A. I. E. E. Journal, April, 1926, p. 365.
2. A. I. E. E. Journal, February, 1926, p. 142.
3. A. I. E. E. Journal, April, 1926, p. 374.

hand control. These considerations do not destroy the usefulness of Miss Clarke's methods which apply for hand regulated system. The methods may also be of value for systems with automatic voltage regulator in case an assumption can be made as to a definite value of machine impedance and a definite value of machine voltage. For example, if the regulator were fast enough to maintain terminal voltage, then machine impedance could be neglected, or if the regulator were merely fast enough to maintain constant flux then leakage reactance should be used. The true static limit would be determined, however, by a transient analysis in the manner indicated in the Evans and Wagner paper.

(By letter): In the verbal discussion, it was not practical to go into a mathematical derivation of an alternative proof for the method of equivalent networks given in Miss Clarke's paper. This derivation follows:

Referring to Fig. 1, the general equations for this network maybe written as follows:

$$E_s = A\,E_r + B\,I_r \qquad (1)$$

$$I_s = C\,E_r + D\,I_r \qquad (2)$$

where the notation for voltages and currents are indicated in Fig. 1 and A, B, C, and D are the general circuit constants. Following the notation used in the paper, complex quantities will be understood without any designating mark but a conjugate will be indicated by a bar over the symbol.

Let us divide equation (1) and multiply Equation (2) by the circuit constant A which gives:

$$\frac{E_s}{A} = E_r + \frac{B}{A}\,I_r \qquad (3)$$

$$A\,I_s = A\,C\,E_r + A\,D\,I_r \qquad (4)$$

Consideration of the above equations will show that they

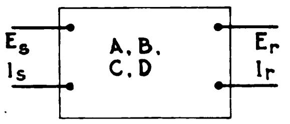

FIG. 1

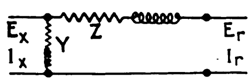

FIG. 2

FIG. 1—GENERAL NETWORK
FIG. 2—SIMPLIFIED NETWORK

correspond to the network shown in Fig. 2 below. The equations for the network of Fig. 2 are as follows:

$$E_x = E_r + Z\,I_r \qquad (5)$$

$$I_x = Y\,E_r + (1 + Y\,Z)\,I_r \qquad (6)$$

By comparing equations (5) and (6) with equations (3) and (4), it will be seen that:

$$E_x = \frac{E_s}{A} \text{ and } I_x = A\,I_s$$

Also

$$Z = \frac{B}{A} \text{ and } Y = A\,C$$

These considerations show that any network with constant impedance branches may be replaced by the network of the form shown in Fig. 2, using an equivalent supply voltage. It will be clear that the conditions at the receiver end for the equivalent network are identical with the conditions at the receiver end actual network. At the supply end, however, the voltage should be divided by A and the current multiplied by A. This simplification is obtained by the use of a transformation constant A, which constant is a complex number and necessitates a phase shift correction for power quantities as indicated below.

$$P_x + j\,Q_x = E_x\,\bar{I}_x = \frac{E_s}{A}\,\delta\,\bar{A}\,\bar{I}_s = \frac{\bar{A}}{A}\,E_s\,\bar{I}_s$$

By consideration of the simplified network of Fig. 2, it is possible to obtain the receiver power and the corresponding angle between supply and receiver voltages by consideration of only the series impedance Z and the phase shift in the equivalent supply voltage from the equivalent network.

Of course, the actual network might be divided in such a way as to permit the use of equivalent voltages at either end of the actual network.

We wish to emphasize the simple manner here employed to find an equivalent network which consists merely in rewriting the equations of the general network in the desired simplified form, and finding the equivalent network that corresponds thereto. The above method has been employed on a few occasions, but the phase shift introduced by the use of the equivalent voltage has been found to be somewhat confusing. The actual limiting angles between supply and receiver voltages may be computed directly from the general circuit constants for the over-all network, and the power corresponding to the limiting angle may be obtained graphically as is brought out in the accompanying discussion by Mr. Wagner.

H. W. Smith: A cursory review of Miss Clarke's and Mr. Nickle's papers indicates that methods are now available for the calculation of the steady-state power limit. These methods substantially agree for all practical purposes. Mr. Nickel's paper conveys the impression that the criterion of stability is the steady-state power limit although on the sixteenth page of his paper, tests are mentioned in which a dead single-phase, line-to-line short circuit, continued for half a second, reduces the power limit to 31 per cent of the steady-state power limit.

I think that all operating men will agree that if this is true, over-emphasis has been placed on the steady-state power limit. In any actual operating system, even though the best known relaying system is utilized, faults will occur, and on high-voltage systems they cannot be cleared in less than one-half second. It thus appears that the study of stability under fault conditions is extremely important.

Mr. Evans' and Mr. Wagner's paper is an extremely valuable contribution. They have developed a method of analysis of stability applied to an extensive transmission system, and this has been checked against actual tests which have been described in Mr. Wilkins' paper. The close agreement between the calculated results and test results seems to indicate that the method of analysis and assumptions made are correct enough for all practical cases. This paper indicates that for fault conditions, the transient stability is less than the steady-state limit. It would be very convenient if we could express this in terms of per cent of the steady-state power limit. This, however, can not be done, and for each system it will be necessary to determine the transient stability by a method of analysis indicated in Mr. Evans' paper.

In deciding on the limit to which systems can be worked the service standards must be considered. It may be permissible to have a system pull out of step under a fault condition that may occur at rare intervals, but if operation must be satisfactory for all fault conditions, the power limit must be considerably less than the steady-state limit.

H. H. Dewey: The general problem of power limits of transmission systems or stability has been before us only for the last year or two actively, and the papers that have been presented so far have left the subject in a somewhat confused state.

The problem as a whole is one that is assuming greater importance, as Mr. Wilkins points out, due to the interconnection of our power systems and the fact that we are endeavoring to make more use of our transmission lines. When we actively started the study of what limitations were important and what to do about it, we naturally started in a number of different directions and there was no very concerted effort made to direct our investigations along the lines that would produce immediate results.

The investigations that were made by the manufacturing companies with their artificial lines brought about certain basic results that were of immense importance. We found out things that we could have easily calculated if we had taken time enough and had got the idea but in our artificial transmission systems these suggestions came up as we noted the results of our tests.

When we had the first papers on this subject at Philadelphia two years ago, practically all of the authors, and I believe most of the men who discussed the papers, were willing to concede that stability depended very greatly on the excitation of our synchronous machines. They were also willing to concede that there was not very much hope of doing anything with our regulators or with artificial changes that could be made in the excitation during a transient. Starting out with that as a basis, we reached limitations of transmission that were surprisingly low. We found that it was difficult to get full rated output out of a generator when its excitation was limited by that necessary to produce normal terminal voltage under the conditions with which we started. That is one point that we come to a conclusion on on our artificial transmission tests that regulators were of extreme importance, and that due to certain facts such as the time element required to put on additional load or the rate at which transients come on, we could make use of artificial regulators and could thus increase the stability of a generator or a generator and its transmission line including transformers and all of the circuits in between.

So that, we feel, is an important point that we have fairly well settled on and I believe that the investigators fairly well agree that artificial regulation is possible and important.

There are a number of things that come before us in the study, some of which make us revamp some of our ideas on transmission. One point that I have voiced a few times and have been questioned on is the effect of charging current, the effect of capacity in our transmission line. It is in effect an absolute detriment. We have always in the past been in the habit of thinking that a long line introduced extra reactance and it was a bad thing to introduce such reactance and cause a voltage drop. We have felt it was compensated for by charging current of the line which had a tendency to hold up the voltage. That is true so far as regulation under specific conditions is concerned but when we are trying to get the last drop cut of the transmission system from the generator to the motor, if there is any charging current in between, that current reduces the excitation required on the generator and the excitation required for the synchronous load and it is an absolute detriment, therefore, because it reduces excitation and decreases the maximum power that can be transmitted. That is a point we dislike to give up but it is there just the same.

I was very much interested in Mr. Wilkins' paper on the test on a practical transmission system and fully agree with him in his statement that artificial transmission systems are of some use in studying the problem but the proof of the pudding is in the eating and we must apply our studies to a practical system and the points that have to be taken into consideration are so many and varied that we cannot reproduce them on an artificial system. We can get the basic principles, however, and those basic principles have been fairly well settled on by our studies on artificial lines and we hope there will be many cases of analyses made such as that on the Pacific Gas and Electric Company's system. The more complicated the system, the more difficulty we are going to encounter in making such a study because there are so many side issues coming in,—points Mr. Wilkins brought out, such as the speed of the relays, the action of the governors, the characteristics of the particular machines you have and the complicated number of machines of varied characteristics.

There are certain things that we know will increase stability. We know that a generator having low reactance helps to increase stability. The characteristics of transformers and characteristics of transmission lines themselves must be taken into consideration. The problem is one we are just starting on and one that is worthy of the combined efforts of all of our best people who have the opportunity to study these problems.

In general, we have not felt that the stability problem is one that was bothering us to any great extent, but usually when we have trouble there are so many things happening that we do know about that we concentrate on the analysis and cure of those particular troubles, and if we knock the system out of step we think it is another happening and one we have let go. Since we have started to study this problem, we have found case after case of pure power limitations that a few years ago we should have passed over as being an incident rather than the real cause of our difficulty.

The main problem before us is the question of the effect of short circuits. It has been pointed out by the authors of the papers that steady-state stability is something that is fairly definite, something we can increase to some extent by careful design of our system and regulating equipment and so forth, but the problem of short circuits is one that we know very little about. We know that we ride through certain types of short circuits. We know that other types break up our system. The analysis of the difference between these varied kinds of short circuits is one that requires more data before we can come to definite conclusions.

On high-voltage lines, we are much more likely to have grounds than we are to have line-to-line short circuits and I believe that has been the history of the 220,000-volt systems in California and the study made of their short circuits last fall brought me to the conclusion that with reasonably fast relaying, we can ride through a ground. It is a pretty difficult thing, however, to run through a phase-to-phase short circuit.

Mr. Wilkins pointed out some of their experiences and on the Southern California System, I found they have had many more grounds on the high-tension line than Mr. Wilkins has had due to the different conditions, but their record of relaying and holding in step has been excellent during those times. But with short circuits on the 66,000-volt system which is veritable network, the short circuits are of the order of 1,000,000 kv-a. when they are phase-to-phase. They have had great difficulty in keeping the system in step. They have dropped out of step fifteen times from the first of January to the first of October. That is an extremely serious condition when the drop is a matter of 300,000-kw. loads during those times.

That, you probably will say, is poor operating but operation hasn't much to do with it; it is the limitations we are getting into in the big system where we get short circuits right in the center of the system.

H. H. Spencer: I think the electrical engineering profession should be most grateful to Miss Clarke for having reduced so complicated a problem to a slide rule and arithmetical basis from the more complicated methods which we have been assumed to use during the past two or three years that the problem has been confronting us. Perhaps the most obvious difference between Miss Clarke's method of calculation, and some of the other methods which have been presented, is her choice of a constant generator reactance. Other investigations have presented methods of analysis which take into account the variation in synchronous reactance in accordance with the Blondel or similar diagram. I think it would be most interesting if Miss Clarke would point out what method is used in the selection of this constant synchronous reactance.

Another point which is perhaps not entirely obvious in the equivalent circuit method of calculation is that it is possible for the receiver network to which a transmission line is tied, to fall out of step *per se*. That is to say, that although a transmission line feeding a network may of itself be stable, the network which is fed may go into instability by virtue of its connection with the transmission line. Just how that works out can be seen by looking at Miss Clarke's example No. 3 on the 11th page of her paper.

Suppose the receiver system had consisted of 100,000 kv-a. of

synchronous generators at the receiver end and these generators had been loaded not to 45,000-kw. but to a load approximating their rating, say, 80,000-kw., allowing 20,000 kw. for spare capacity. Under such a set-up, it is quite possible that line would be able to transmit the calculated load of 132,600 kw., but that a reduction in the voltage at the receiver end while not producing instability between the receiver load and the sending end generators, would produce instability between the synchronous load and the receiver end synchronous generators.

In regard to the difference between steady-state and transient power limits, methods of analysis are certainly developed at the present date to the point where given the same assumptions, two engineers will come out with the same answer. The difference between the answers which are obtained from transient stability analysis lies, I believe, in the difference in the fundamental assumptions in regard to the flux relationships in the synchronous apparatus at the two ends of the line.

Now the problem of flux relationships in synchronous apparatus is not one of novelty, but on the contrary is one which has been dealt with for a long time and with consistent success by designing engineers. It is necessary for the engineer who would calculate stability, or power limits, simply to compute the flux relationships which exist under certain known conditions by means of perfectly definite methods which are in common use. Having disposed of the problem of flux relationship, the difficulty of the stability problem very largely disappears and the power limits are readily calculable.

If we concede that during a particular transient disturbance the flux in a generator or a synchronous motor remains essentially unchanged, then I think any engineer would have a tendency to feel that the power of limitations imposed during operation under the conditions which led to the development of the initial flux would obtain throughout the disturbance. Thus switching operations such as the dropping of a generator or one of two parallel transmission circuits will introduce no power limitations below those imposed by steady state operation since disturbances of this sort have no tendency to reduce materially the flux in the synchronous generators. Short circuits, on the other hand, which do reduce the flux in the synchronous apparatus may very possibly impose power limits appreciably below these encountered in steady state operations.

Several single-phase, short-circuit analyses which have been studied during the past few months have shown that in a system of ordinary design, the steady-state stability limit is very markedly reduced by single-phase short circuits to ground. However, by means of changing the circuit set-ups, introducing a zero sequence reactance in the transformer windings, or using neutral reactors, the steady-state stability limit of the transmission system can be very closely approached.

H. K. Sels: In order that I may present clearly and concisely a number of points in some chronological order, I am taking the liberty of reading a prepared discussion. I do not wish to deal in personalities but to present such criticisms as I have from the purely abstract viewpoint of an operating engineer for a large and extensive system—particularly since the papers have not been in my hands long enough to fully acquaint myself with their respective contents. After three years of theoretical and experimental investigations I am more interested in the questions,—what has been accomplished and whither are we bound? No single organization seems to be responsible for the headway that is being made and I offer that as a hint to some of our several transmission committees.

The question of stability is as old as the alternating current art itself. We have always been confronted with the problems of synchronizing power between large generating stations, "hunting" of synchronous motors and the stability of rotary converters. A large number of papers have been presented before the Institute relating to these problems. The impression one gets from the papers which have been presented on the subject of stability is that we have discovered something radically new, some vital thing in which our power systems are unduly weak. Such is not the case and our methods of electric distribution are no weaker than they have been, by virtue of this discovery. However, what we do have that is new is a broader vision of the problem and the relation of its elements, and new methods of attack, and we hope, after all the facts have been analyzed, that we will obtain a solution which will extend the power limits of transmission to the ultimate.

Fundamentally, what we are really interested in is the power limits of a transmission system. A large number of factors determine the power limits of a system. It may be the current carrying capacity of the wire; it may be the economical amount of power that can be transmitted over a given line before it pays to build additional lines and maintain the same continuity of service, or it may be the question of stability of operation, which are the subjects of today's papers.

Psychologically I think it would be better for us to speak more in terms of the power limit, remembering that stability is only one of the important factors involved.

I believe everyone is over-emphasizing the relation of stability to high-voltage transmission. Of course it is true that stability is more likely to fall within the economic power limits of transmission at the higher voltages, but this does not reduce the importance of stability at all voltages and on all systems. Every operator is familiar with the losing of load or the dropping out of synchronous apparatus during system disturbances and fundamentally this is nothing more than the effect of instability. Therefore any improvements for stability apply equally well throughout the system.

Just to refresh my memory on the general trend of opinion on the various factors entering into the stability question, I reviewed recently all the papers and discussions that have been presented before the Institute. From an operating viewpoint I was very much impressed with the technicalities and, to me, the impractical viewpoints which were expressed. I believe that the average engineer would be hopelessly lost in attempting to follow through calculations on anything more than a very simple transmission system rather than a large interconnected system where the attempt is made to keep short circuits as low as possible by using synchronizing buses with reactors between individual generators and other complications used in the layout of the modern system for dispatching load; in fact it is very much like the mathematical conundrum of trying to solve a problem having more unknown variables than equations.

In addition to the factors outlined by the various authors, let me indicate for a moment some of the multitudinous conditions which the operating engineer must consider in making any calculations on stability. First, today we have a certain distribution of power stations serving a given load in a given territory connected up with a certain arrangement of transmission. Tomorrow we have a more efficient generating station coming into operation, a new arrangement of transmission to new load centers, which entirely alters the fabrication of the system. In actual operation the load conditions obtained hour by hour, day by day and year by year, change on account of the relative efficiency of the generating units on the system, the variation in load and different set-ups of lines in and out of service due either to failure or ordinary maintenance. All of these features only serve to make an intricate problem more involved. In attempting to determine a method of calculation which can be used with some degree of accuracy, I believe we should use those assumptions which we find agree the closest to actual operating tests.

Today's papers indicate more than ever that the methods of calculation used by the different engineers do not differ greatly in theory, but there does seem to be some difference of opinion as yet on the assumptions to be made and whether the steady state or the transient state is more important. These differences

apparently account for the divergence in the results of calculations by different engineers. As I have already brought out, the problem is so intricate that at best the solution is a cut and try process in which your methods of calculation and assumptions must conform with the results obtained by experience. For this reason I believe that for the present at least we shall consider all calculations only qualitatively and not accept calculations by separate engineers as comparative unless made on the basis of the same assumptions. For example, I might agree with the general shape and relationship of the curves in Fig. 17 in the paper by Messrs. Nickle and Lawton, but not agree with the maximum power scale due to some difference in my calculations.

With regard to the relative importance of steady-state and transient conditions, I believe it is evident that in cases dealing with high voltage, long distance transmission where the stability limit falls within the economic power limit of the line the steady state performance of the line will be of primary importance, because with such a large amount of capital tied up in the transmission system every means possible will be used to make failures on the transmission practically unknown. While the transient state does not enter so much into economics of transmission, it should be expected that continuity of service to local loads as well as the extreme importance of keeping a large high voltage system operating continuously as a whole will make this a factor not to be overlooked. In the case of lower voltage and shorter distance transmission, we can point to case after case of both major and minor importance in which some disintegration of the system takes place during a system short circuit. In actual operating experience I have yet to hear of the case where a system designed to operate in parallel has fallen apart due to steady-state conditions except where the static limit was reached in the Southern California Edison system within what we might say is the economic emergency capacity of the line. However, I should like to ask what experience shows here that transient stability is not an important factor. Before too much discussion is entered into on steady-state and transient stability, it would be apropos to have the terms defined, and we may find more of us in agreement than is apparent at first. Personally I classify the steady-state stability limit as that load which breaks down a system when slowly applied and the transient stability limit as that load which breaks down a system when suddenly applied or during switching operations including short circuits. It is conceivable that under certain conditions of small load increments or minor switching operations, the two limits will be the same when so defined. Summing up the relative importance of steady-state and transient stability, here again I believe we must resort to actual operating experience to tell us where our weaknesses lie. It is commended that the various investigators review the interruption records of some of the operating companies.

If we must rely so much upon actual operating experience, you may then ask, "What are we gaining by all our calculations?" As an operating engineer, I turn to the manufacturers of electrical equipment for the answer to this question. There is relatively little that can be done in changing the characteristics of our transmission systems so as to get more power per circuit over them, but there is apparently much that can be done in the development of terminal equipment. As already indicated, calculations are of more use as a qualitative measure than as a quantitative measure, particularly in reducing the annual bickering as to the relative merits of designing equipment.

There is a point to which I have been leading in this connection and that is as to whether the design engineers of terminal equipment are making its characteristics to suit special cases or whether the improvements are to take the form of a general design which will be suitable to meet the ever-changing conditions in a developing system. For example, I believe these improvements in design should be of a general nature because if we picture the developments of a twenty- to thirty-year period in a large interconnected system, the various load centers in the network will pass through a number of stages in which machine characteristics of only a general nature will apply. Of course for periods of a longer time, we can, by the usual methods of accounting, charge off old equipment and buy new of suitable character. If we take a broad vision of the problem at this time, however, we have an opportunity for obtaining economies which otherwise might be lost.

I should like to call your attention to the related problem of short circuits. Broadly speaking, a short circuit on a system is merely a certain type of load, of which the characteristics are rather elusive, but we can assume conditions covering a wide range in the hope of representing the actual conditions and apply the same methods of calculation carried out in studying stability. Here, then, we have a new method of investigating short circuits which takes into account the various phase relations of the prime movers, giving us a better picture of the duty required of our oil circuit breakers. From one standpoint we may be pessimistic in making calculations on the assumption that the sources feeding the short circuits are all in phase, but on the other hand I believe we have been optimistic in the way our circuit breakers have been performing in interrupting large short circuits, the value of which has been obtained from short-circuit calculation on the d-c. tables. It may seem somewhat unfair to add to the criticisms of our circuit breaker performance but it is a question which is closely allied to the stability problem. The whole thing is like burning the candle at both ends. On one side, we are trying to make our systems more stable which, in a sense, means greater concentrations of power and greater short circuits, and on the other we are trying to keep our concentrations of power to a minimum and thereby relieve our short circuit requirements. How can we have our cake and eat it? The only possibility in view along this line is to lay out small individual systems interconnecting them for diversity and reserve purposes only, but this step is in direct opposition to present tendencies in operating economies.

It is easy to sit here, and I may as well add, in our offices, luxuriously basking in the sunshine of a successful convention or conference, and dispose of this and that theoretical possibility with some oratorical gesture, but we must remember that experience often reverses the best of our intentions. I might illustrate this by an actual happening. The continuity of service on a given substation bus having two independent power station sources and two independent feeders from each of these was questioned and the statement was made that a shutdown was well nigh impossible. Approximately six hours later the impossible happened and the substation had an interruption measured in hours and the trouble was not a bus fault. We must remember that there are a number of links in the chain between our design tables and the distribution of power to the ultimate consumer. We are dependent upon Tommy Riley, Buck Jones, Ted Flinn and the rest of the boys on the firing line, who, in weather like this, keep maintenance on switching to the point where we may expect fast relaying. The more we can incorporate improvements in the inherent characteristics of the apparatus itself the more we will remove the personal element and for that reason we should proceed slowly in getting greater stability with additional equipment that may not function at the critical moment. It is easy to set up operating conditions but often quite another matter to obtain them. Therefore, I believe it is more practical and economical to first improve the characteristics of equipment now in general use and then turn to the possibility of adding other auxiliary equipment.

C. A. Powel: There are two points mentioned by Mr. Wilkins, and also by Messrs. Evans and Wagner, upon which I wish to comment. The first is the character of system oscillations at times of a fault to ground. Ordinarily, one thinks of a short circuit as reducing the energy output of a generator. How-

ever, in the case of a fault to ground on a large transmission system, the effect may be to actually increase the generator power output. This is due to the resistance in the ground connections from the faulty conductor to the transformer neutral.

Three records have come to my notice, and in each of these cases the generator output was actually increased, and in two of them the prime mover input was also increased by the opening of the gates. While this evidence should not be construed as meaning that all faults to ground will increase the power output of generators, it certainly does substantiate the position which has been taken that the resistance of faults to ground must be carefully considered.

The second point is the fact brought out that there is no particular value for the transient limit of a transmission system. Loss of synchronism at times of fault is dependent not only upon the system layout, but also on the load being carried and on certain speculative elements as to location and character of the fault. The point seems to me important, because it involves the whole question of rating of transmission systems. If the operation is such that it is permissible to pull apart every time a fault occurs, then obviously it will be possible to carry a load not far from the static limit. If, however, the transmission system is expected to ride through the majority of troubles, the power transmitted must be kept considerably lower.

In view of these considerations, it is desirable to obtain data

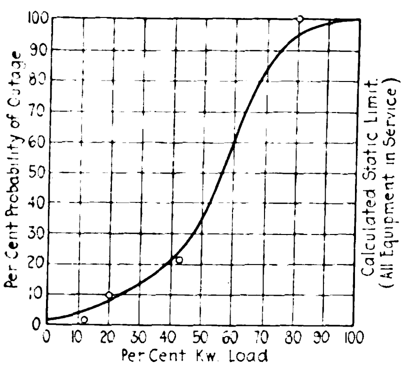

Fig. 3—Probability of Outage of Transmission System as a Function of Load in Case of Fault

as to outages and to plot the results in the form of a probable outage curve as a function of the load. Such a curve is shown in Fig. 3. All faults on the transmission line, and in addition, faults on secondary systems which produce outages, should be considered. It will be noted that the curve shows a definite but small probability of outage when the system is carrying zero load; such outage, for example, might be due to an operating error. The curve also approaches 100 per cent outage as an asymptote at the static limit. It becomes very steep in the middle portion.

The smooth curve which has been drawn is based on the limited amount of data which has been obtained for a particular system. While more complete data will probably change the exact points through which the curve would pass, it will not change its general shape.

The shape of the load curve on the transmission system must also affect its rating. If the power transmitted varies so that its peak value is only of short duration, the maximum rating can be kept higher with the same risk of outage, because the probability of faults is independent of the load.

Stability and not the losses in the lines determines the rating of a transmission system. Increasing the size of conductors will not appreciably increase the stability, and consequently the question of rating is of prime importance when deciding on the size of conductors to be used in a transmission system. The expenditure for extra heavy conductors may not always be justified.

R. E. Doherty: I think that the Institute is to be congratulated on having the papers which have been presented at this session, particularly the one of great importance, Mr. Wilkin's paper, which, for the first time, gives some actual operating data regarding these problems.

I should like to say a few words with respect to methods of calculations which have been referred to in various papers. A new subject, or a new phase of an old subject, came up recently, (within the last few years), and independent investigators attacked that problem. New nomenclature appeared, and each man has his own notion about those matters. Until they are standardized, we always shall have with us the well grounded objection of the next-to-the-last speaker, that he doesn't know what every one is talking about, and I gathered that he doubted whether the authors did. I have sympathy with his bewilderment.

Each one of us who studies this problem must make some simplifying assumptions. I think that there is one point on which we are all agreed; that a complicated power system network is not amenable to rigorous treatment by mathematical methods as we know them now, and I doubt that it ever will be. It is therefore necessary to make certain simplifying assumptions. Mr. A may make one assumption, Mr. B another assumption, and so on; but before he acts on it, you can rest assured that he is going to have some data or actual experience, some basis for his conclusion before he takes any step toward actually applying it. And if their conclusions on which action may be based are in substantial agreement, it seems of little avail, and certainly misleading, to publicly emphasize trifling disagreement of experts on certain details. While I may appear to be letting the cat out of the bag, so far as this apparent disagreement is concerned, I wish to state that when it comes down to brass tacks on a given proposition, to a study of some proposed system, the agreement among engineers seems to be pretty complete on what can be done and what cannot be done—which indicates to me that the more important factors are generally understood and agreed upon. I am sure all of you who are not daily living with this problem, would rather have those who are discuss and settle these disputed details over a table rather than here on the floor of the convention. I think one of the first things that could be settled in that way is nomenclature, and I propose that it should be done.

Just one word about this discussion of static stability and transient stability. I don't like to talk about stability. I share the view of a previous speaker, that "power limit" is a perfectly definite thing. It happens that the maximum power in some cases is also the limit of stability, but it is not in all cases. You can have a maximum power which is not the limit of stability, but I think all engineers are agreed on this: That there is a definite maximum power which can be transmitted over a given system under steady state at normal voltage. It is a perfectly definite thing, and everybody will agree on the value of that limit. And if so, let's talk about that limit.

We have found on investigation that if one throws on any load up to that limit, and the system is controlled by an ordinary vibrating commercial type regulator, the system will carry it. It will not lose synchronism. There may be such cases where synchronism would be lost, but we haven't found them. So long as the power to be carried is not greater than the static limit under the new condition—for instance, when a line section has been switched out—you can get away with it. In connection with this, I agree with the conditions mentioned at the top of page 2, second column, in the Evans and Wagner paper. The supposition is that if you have adequate relaying system and can promptly clear a line-to-ground fault, it is possible to carry through it.

In connection with this, Mr. Nickle states in his paper that

the static limit appears to be a criterion for the study or determination of power systems, and I submit that this is a reasonable position to take. It does not say that there are no other criteria, and that if it is satisfied, the system can not fall out of synchronism. It does say, however, that if it so happens, during a transition from condition *A* to condition *B*, the system is so regulated that it could carry condition *B* under steady state, then it can. by virtue of that regulation and the inherent electrical and mechanical characteristics of the synchronous machines, carry through the transition and remain in synchronism. Now if this were true in all cases, the steady-state limit for the worst condition *B* would be a comprehensive criterion. Our conclusion is that with proper regulation and, excluding short circuits, it would be generally true. It is probably true in the usual line-to-ground short circuit. However, whether or not we speak of the steady-state limit as a criterion, I earnestly submit that it is a definite figure which is characteristic of any given system, and is a quantity which any informed engineer with the same data will arrive at. It therefore constitutes a sort of a bench mark for reference.

I wish to add a word about high-speed excitation. Two elements are essential in an excitation system in order to increase the maximum power beyond the steady-state limit to which I have just referred. One is an exciter of sufficiently high magnetic speed. The other is an automatic regulator which would properly control the exciter. The high-speed exciter is easily obtained. However, no commercial regulator within our knowledge at the present time has the required characteristics to thus utilize such an exciter. The mercury-arc rectifier scheme[1] which was discussed at the Seattle Convention has the necessary inherent qualities. With proper regulator control there should be no discontinuity between the steady-state power limit obtained with the standard exciters as ordinarily regulated, and the limit obtained by the extremely high-speed excitation of the rectifier, so long as the increased exciter speed is properly applied. And while I reiterate that inherent characteristics of present day commercial vibrating regulators prevent their accomplishing this, it is nevertheless hoped that a regulator of proper characteristics may presently be available.

To sum up my discussion, it is certainly gratifying that all engineers who are studying these matters seem to be coming to the same general conception of this whole problem. There are certain trifling matters concerning which they are not yet in complete agreement because they have started out from slightly different bases, some thinking one assumption is more important than another. But these are not of general concern. The whole problem, I say, is sifting down to a narrower range in which we can all view it from the same angle and agree, provided we are careful about defining the terms we use.

C. L. Fortescue: I want to express my appreciation of the ingenious method Miss Clarke has developed to determine the static stability limit. I also wish to say, however, that the methods that have been used before are in reality no more complicated than Miss Clarke's method but the apparent simplicity of Miss Clarke's method is due largely to the able way in which it has been presented.

Regarding the paper by Messrs. Nickle and Lawton, I want to congratulate them upon this paper. It is an extremely readable paper. I want to emphasize in discussing this paper not the apparent differences in opinion between our group of papers and this one, but more the points on which we have come to an agreement. There is a tendency in discussions to pick out the points of disagreement and discuss them only. As a result of that, those who read the discussions say, as I heard Mr. Roper remark, "Well, we can't make head nor tail of this matter. Some say this is black and others say it is white." The static stability limit is a very definite limit. One might say it is an invariant of a given system. It is quite a definite value and can be determined without difficulty. I shall go Mr. Doherty one better and say the static stability limit as defined by constant excitation is one of the criteria of the stability of a system—not the criterion, but one of the criteria.

In connection with this static stability limit, in considering ways and means to raise this limit, we found with high speed automatic regulators we were able to get quite an appreciably larger amount of power over the circuit.

Now I am bringing out this point not to emphasize the point of difference, but because this artificial stability has an element of hope in it. If you can do it with a regulator today, you may be able to get a regulator that will do it still better tomorrow. You will surely be able to get more power over a given line tomorrow. Maybe the automatic regulator of special design will be the answer; maybe an inherent regulator scheme will be the answer. We don't know now, but one of these days we will know.

Now regarding the transient stability as one of the criteria of operation: I want to say that after reading over the conclusions in the paper I was rather struck by the fact that transient stability wasn't considered of great importance, but on reading over the paper itself, I found data presented there that led me to say that transient stability was just as much of a criterion as the static stability.

One statement in the paper, page 16, calls attention to single-phase faults and points out if the fault is removed instantaneously, the load can be carried right up to the stability limit. Now if you remove a fault instantaneously, you are doing exactly the same thing as if you cut out a section of line on a loaded transmission line instantaneously. And we know if you cut out sections of loaded lines, the effect on the load limit is very small, so I think that is the answer to that.

As a remedy, mention is made of quick operating relays; that is part of the remedy but we must go a step or two further than that. We must have quickly operating circuit breakers and we must have adequate voltage regulating systems, either high speed or inherent, and we may possibly have to help out with the governing system and also consider the effect of resistance of the fault. I wish to point this out because I myself reached somewhat different conclusions from those of the authors from the data they present in their paper. We can't say that one limit is more important than another limit. We have several limits. We have the static stability limit, and if you raise that, you also raise the transient stability limit as a general rule, so that we have several loopholes to follow in order to solve this problem.

As to methods of calculating transient stability, I may say that we have found it practical to calculate even relatively complicated systems by the point-by-point method. It is of course a long drawn out tedious method. There is no doubt a technique will be developed in the course of time to enable engineers to calculate power transients in more complicated types of systems. In other words, the present methods are cumbersome and long drawn out but they will be improved and perfected in the course of time.

We do not dissent from the opinion that a dynamic model may be evolved, but we insist that such a model must take into account the essential facts, the most outstanding of which is that the differential equation of the motion is not linear. The condition with which we are concerned in transient stability is that unless we get instantaneous removal of the fault, it does not permit of the use of approximately the linear form in analysis. In fact, the problem is similar to that of a pendulum and the difference between the two problems is the difference between the cycloidal pendulum and the simple pendulum, between the harmonic motion and the elliptical.

I bring this point up because I think Mr. Nickle in the course

1. *Fundamental Considerations of Power Limits of Transmission Systems*, by Doherty and Dewey, A. I. E. E. JOURNAL, October, 1925, p. 1045.

of time will undoubtedly get the right kind of dynamic model to find the answer to the problem in the proper terms.

As to the effect of machine characteristics, the importance of machine characteristics has been emphasized by the group of engineers to which I belong. Machines designed according to present practise must incorporate the necessary stiffness, to use the authors' term. This may be done by designing machines with lower synchronous impedance, that is, with long air-gaps or saturated poles. This applies to generators and synchronous condensers. In addition to this, we must have voltage regulators quickly responsive to changes in voltage.

An alternative method which may develop is the compensated machine which may be a generator or a condenser. Partial compensation in the case of a generator may be considered of advantage. Investigations on compensated machines are being carried out now and data is being obtained which will be available in due course.

In regard to the intermediate condenser, the authors have indicated a substantial gain with sufficient condenser capacity. While the capacity requirements as represented by them are large, it need not worry us as there is no doubt that in due time the right kind of machine which will give the desired results with smaller capacity will be developed.

W. P. Dobson: Mr. Wilkins evidently relied upon telephone signals to obtain simultaneous oscillograph records at widely separated stations. In 1912 and 1913 the writer, during an investigation of transients on 60- and 110-kv. systems, made use of an automatic attachment to an oscillograph to accomplish this result. The closing of a switch on the oscillograph table operated the high-tension breaker, the film-motor and shutter in proper sequence to obtain the desired record on the film. Circuit breakers in distant stations were connected to the oscillograph control by means of the system telephone circuits. It was possible to obtain records of transients of short duration on a standard 12-in. film and satisfactory records of transients of over one second's duration were obtained with a 42-in. film. The apparatus was designed by Professor H. W. Price of the University of Toronto and was used on the lines of the Toronto Power Co. and the Hydro-Electric Power Commission of Ontario over a period of 18 months. Several hundred records were taken with a negligible number of failures. It is believed that this was the first instance of the application of automatic control of an oscillograph for this purpose.

H. B. Dwight: On the 11th page of Miss Clarke's paper, there is a diagram in which leading reactive kv-a. are plotted downward. This is typical of the papers by several authors. There is also a group of writers who draw this type of diagram with leading reactive kv-a. plotted upward, the same way that leading reactive current would be plotted. It is an inconvenience to have these two opposite methods in use, and as diagrams of kw. and reactive kv-a. are of somewhat frequent occurrence for various purposes, it seems that the time has come when it is appropriate for the Institute to give a decision as to whether leading reactive kv-a. should be considered positive or negative, and should be plotted upward or downward in diagrams.

J. W. Legg: Mr. Wilkins deserves much credit for recognizing the value of reliable high-speed records, and for insisting on having apparatus capable of giving reliable graphs at these high speeds. The Esterline graphic instruments used in these tests were too sluggish of movement to warrant a high-speed chart until they were reconstructed with greatly increased restoring torque and more than 50 times normal power input. This necessitated a battery of special transformers and special switching schemes to throw the graphic instruments out of the circuit after operating less than half a minute, to prevent excessive heating.

In 1914, while still a student, the writer conceived a truly portable oscillograph to operate with a low-voltage incandescent lamp, and to have wattmeter elements, and other effective-value elements, as well as the standard elements for instantaneous values. The ease of obtaining truly high-speed graphs, freely crossing one another, appealed to the writer as being worth the inconvenience of photographic development. A daylight-loading film holder was conceived then but not developed and perfected until 1921. In spite of this improvement in film-holders, all effort was expended to develop high-speed graphic instruments requiring no photographic film. Progress has been made in this line, but the demand for higher and higher speed records (with correspondingly higher-speed movements) has surpassed all improvements in standard graphic instruments. This is shown very clearly in Mr. Wilkins' paper. The standard high-speed (so-called) graphic instruments were of practically no value for these important tests until remodelled and forced at fifty times normal input. C. F. Wagner saw the limitations of these instruments, after all the improvements he had made, and made up several oscillographic wattmeters to be placed inside our standard, portable oscillographs, and in separate cabinets using standard oscillograph lamps, lenses, film holders, etc. These confirmed the writer's predictions and proved very successful in these tests.

Several years ago the writer figured on an instantaneous, polyphase, reflecting, wattmeter-element, with a natural period of approximately 2000 cycles per second. A single-phase wattmeter element, with a natural period of 5000 cycles per second, would be very simple, but not particularly valuable on account of the high (double) frequency oscillation of the power wave on a-c. lines. The quick-acting (but not instantaneous) elements, pushed through for these tests, proved so successful that they will be commercialized, in an improved form, very soon.

A nine-element portable oscillograph, considerably smaller than its three-element predecessor described in the JOURNAL of February 1923, has been designed to give nine simultaneous records on one 7-in. width of film. Three of these oscillograph elements may be replaced by high-speed wattmeter elements, or by other effective-value elements when they are developed. Such an instrument will be ideal for stability tests, and for operation on chance disturbances. A daylight-loading long-film holder has been developed to take films 6½ in. wide and either 3, 6, 8, 16, or 24 ft. long. Twenty-four-foot films were used for the first time in these stability tests, passing through in less than six seconds. For lower speeds the film-holder can be made to operate quite reliably for daylight-loading and daylight-unloading.

During the discussion of the writer's paper, in 1923, on "Expansion of Oscillography," J. R. Craighead seemed to doubt if the oscillograph could be made to function, automatically, quickly enough to show what happened before the oil circuit-breakers functioned. All that the writer claimed then, and more too, has been done since then. Our portable oscillographs have been set up in substations and have operated, repeatedly, on chance disturbances, and have given valuable information as to the disturbance and breaker operation. Furthermore the new single-element oscillograph (the OSISO) can be set up to record chance disturbances within less than one-thousandth of a second after the closing of a quick-acting relay. The 4-volt lamp is initially excited by a condenser charged to 110 volts, d-c. The lighting of the lamp is quick enough to obtain a perfect oscillogram of the chance rupture of the arc in a quick-acting circuit breaker on d-c. lines. With the proper quick-acting relay, operating on the steepness-of-wave-front principle, the oscillograph will function perfectly within two-thousandths of a second after the very start of a short circuit, before the quick-acting breaker can reduce the short-circuit current. The photographic film must be kept rotating all the time, for such extremely quick operation.

The advantages of such apparatus are being better and more universally recognized, and oscillography will continue to expand and be a greater and greater help to others besides the electrical manufacturer.

Svend Barfoed: In designing transmission systems to safely carry a specified load, I have in the past used methods that are very direct. They involve the use of diagrams in which the various factors affecting the power limit of a transmission system appear together and may thus be studied more easily. As yet I have not found any necessity for transmutation of the diagram and method into others which, as far as can be seen, are the exact equivalent. The accompanying diagrams illustrate such a study.

Fig. 4 has been described several times. The load lines are shown advancing by eights up to full load; to scale they are meas-

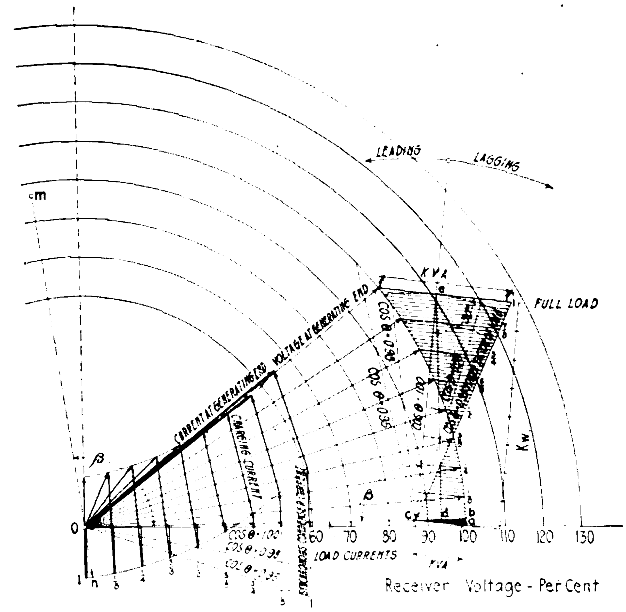

Fig. 4—Typical Regulation Diagram for High-Capacity Transmission Line

ured in position in kw. The magnetizing power is measured parallel to the load lines to the same scale in kv-a., being for example $c\,F$ at unity power factor of load at full load or $F'\,F$ at a power factor of 0.95. The magnetizing effect of the charging current is given by $a\,c$. Thus all factors affecting the trans-

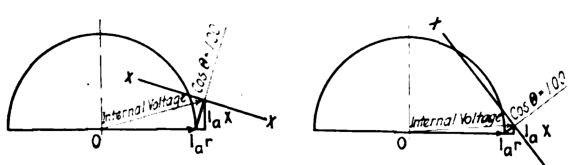

Fig 5 Fig. 6

Figs. 5-6—Generator Diagrams for Different Ratios $\dfrac{I\,r}{I\,X}$

mission limit of power of the line and transformers is had at a glance. It is at once apparent that all factors are very definite and do not admit of discussions of a qualitative nature. For any given relation the line and the transformers have characteristics which are fixed and quantitatively known. It can easily be seen that the smaller the resistance compared to a given reactance the higher the power limit, and highest for zero resistance. In other words, the more nearly vertical line $c\,e$ is, the higher the power limit. On the other hand, with nearly zero reactance the power limit would be very low indeed. The criterion is the tangency of a load line to any one of the circles shown on which it may be desired to operate. Tangency represents the static load transmission limit. Swinging the unity power-factor line $c\,e$ around c as center to the right, representing a designed decrease in reactance for the same resistance, makes

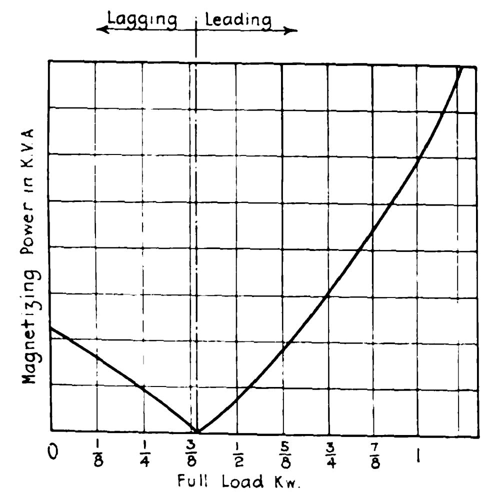

Fig. 7—Magnetizing Power Required from Synchronous Machines on System (From Diagram Similar to Fig. 4)

the maximum load lines become tangent to the circles at smaller and smaller loads and when finally the load lines become nearly vertical the ability of the system to transmit power almost vanishes. It is thus seen that in order to transmit power with alternating current the proper relation between resistance and reactance must prevail and it is evident that low resistance lines are highly desirable since the reactance of the line can be changed but little due to clearance limitations. Similar reasoning holds for the transformers, but with them it is also desirable that the reactances are no greater than required for the strength of the

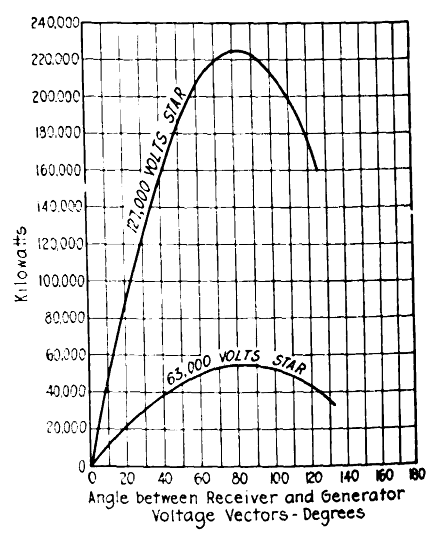

Fig. 8—Static Stability Curves—200 Miles of Line (Plotted from Diagrams Similar to Fig. 4)

mechanical structure during short circuit. At previous meetings when power transmission limits have been discussed, the characteristics of the synchronous machinery have been included, but in no very definite manner. It is with respect to the synchronous machines that it is ventured to hoist a warning signal. It is seldom that a large power plant contains but one machine. If there are several it is imperative that they have such character-

istics that they will operate properly in parallel under all conditions of load and can readily be synchronized. There must be no hunting between them. If for the sake of increased power transmission limit the synchronous reactance is very much reduced, hunting will surely occur between generators running in parallel in the same station, and stability, possibly, may only be secured again by adding reactors external to the machines. This is an old story and is visually shown in Figs. 5 and 6. In Fig. 7 the ratio $\frac{I_a r}{I_a x}$ permits the proper synchronizing force to develop between machines due to a large amount of power possible of transmission between them. In Fig. 6 the ratio $\frac{I_a r}{I_a x}$ is such that the limit to the synchronizing force is very quickly reached with the machines liable to fall out of step.

The effect of the load power factor is given at once by these diagrams, and there is nothing vague about the amount of magnetizing power required to compensate for power factor, either for voltage regulation or for a given power transmission limit. The synchronous condenser is a very admirable machine to give or consume magnetizing power in the required amount. It will perform exactly as desired if the V curve of zero power load coincides with the magnetizing power curve of Fig. 7.

From the above it is seen that the line and transformer characteristics and the charging current do not lend themselves to a discussion of power transmission limits. They are to be considered known and fixed within narrow limits. As long as we transmit power with alternating current, the charging current cannot be removed and to say that it is detrimental to a higher power limit is like saying that the current flowing in a coil of wire is undesirable because it heats the coil.

The power limit of a given transmission system is therefore influenced chiefly by the characteristics of synchronous apparatus. I accept the statement that the machine designers know how to design machines for maximum transmission of power. That being so, the transmission line designer would like to know in what manner this is done. He would like to know how the synchronous reactance is apportioned between self induction and armature reaction, how compensated for, whether means to affect a quick response to excitation power is counteracted by means to affect damping of power swings, and whether a machine designed for maximum power limit is a suitable machine for installation in a plant where there are several which must safely operate in parallel on the same bus bars.

It has been said that power factor has much to do with the power transmission limit. To be sure it has, but in a perfectly definite manner. Power factor lagging means that magnetizing power must be furnished by synchronous machines either at one end of the line or both; power factor leading means that magnetizing power must be absorbed by synchronous machines or by some other variable tractor. If the rate of change in magnetizing power is such that the excitation power of the field structures cannot follow at the same rate, oscillations will be started. Tests on actual systems cannot reveal much in this connection since the magnetic structures cannot be changed. Such tests belong on the test floors of the manufacturer. With machines of conventional design it appears that transmitting power at 220 kv. up to 250 mi. is safe when the lines are loaded to one ampere per 2200 cir. mils and condensers located only at the receiving end. This can be improved by suitable engineering of the line itself. A discussion of this would, however, lead too far at this time. Only this,—there must not be added further apparatus in power houses, substations or elsewhere until circuit breakers for 220-kv. operation have been improved to the point where they no longer constitute the present limit to transmission of power. The circuit breaker must perform its function without destroying itself too soon and it must open the circuit at such a rate that a power arc on the line will not have time to seriously injure the conductor. The circuit breaker must be relied upon to transfer without distress the energy from a line section in trouble to a parallel line. The normal energy to be transferred is of the order of 130,000 kw. It is comparatively easy to compute power swings and to provide a sufficient margin of safety. It is far more difficult to design economically a system where disturbances causing power oscillations will inherently be reduced to a minimum. The first problems to solve are 220-kv. circuit breakers and line insulation.

F. L. Lawton: It is certainly in order to compliment Mr. Wilkins and his associates on the courage and initiative displayed by them in attempting investigations of system stability on a power system of the magnitude described. Further, the addition of field tests of this type to the theoretical studies undertaken in the past few years affords an opportunity of passing judgment on the assumptions made in those studies.

It is indeed encouraging to note the real agreement between the conclusions reached by Mr. Wilkins and those presented by Mr. Nickle and myself, today, and also those in a recent paper[4].

The writer disagrees with Mr. Wilkin's observations anent the place filled by the use of artificial lines and miniature equipment. It is, of course, true that test data, whether obtained on an actual network or on miniature systems as used by Mr. Nickle and myself, apply only to specific conditions on given systems. However, and this is important, *it is virtually impossible to assign the right values to the factors affecting the stability of a real network*, of anything like the complexity of the Pacific Gas and Electric Co.'s transmission and distribution system. With the miniature system, methods of analysis can be studied, actual cases[5] checked, and *the methods of analysis may then be applied with real confidence in the soundness thereof to the solution of stability problems.* In this respect, the miniature systems with synchronous apparatus up to a few hundred kv-a. capacity have been of great assistance but it is not suggested that a 225-kv-a. system be used for the solution of stability—or rather, power limit—problems. For these there are available:

(a) The miniature system of Spencer and Hazen[6].
(b) The equivalent-circuit method of Nickle[7].
(c) Proven methods of computation.
(d) Experience.

When anyone conversant with the difficulties involved in analyzing system power limits by theoretical methods visualizes the physical data applying to the system in Fig.1, he will have a better appreciation of what a miniature-system method of stability analysis means.

When results of good engineering accuracy, directly applicable to proposed or existing power networks, can be obtained relatively easily and expeditiously by use of a miniature-system method and proved principles, it is presumed that they will be used and "actual quantitative values for this fundamental data" will *not* need to be "measured." Such miniature systems and principles, it would appear, are already available.

Regarding the contention that system stability, as a problem, is inextricably entangled with operating economics, this is largely true but, nevertheless, good progress can be made in determining the power limits of transmission systems under the majority of circumstances likely to arise.

The results obtained by Mr. Wilkins when the 220-kv. line at Pit No. 1 was switched out under a load of 24,000-kw. agree quite closely with those obtained by Mr. Nickle and the writer. I think that a little closer consideration will convince Mr. Wilkins that the cause of the greater disturbance on closing

7. *Oscillograph Solution of Electro-Mechanical Systems.* C. A. Nickle, A. I. E. E. JOURNAL, Dec., 1925, p. 1277.

the line was entirely due to the effect of the line charging current in changing the phase and magnitude of the "open line" voltage relative to that on the generator side of the closing circuit breaker.

In connection with the above, it might be added that an oscillographic wattmeter with characteristics similar to that described was used throughout the major part of the miniature-system tests previously referred to.

To conclude, it appears that the first extensive investigation of power limits on an actual system of a fairly high degree of complexity leads to conclusions in substantial agreement with those presented by Mr. Nickle and myself, as well as others, entirely from the results of miniature-system studies, coupled with field experience and office analysis.

A. P. Mackerras: A pleasing feature of this paper is the use of graphical methods. Graphical solutions are usually sufficiently accurate for practical purposes; and, in addition to their rapidity, they give a better physical conception of the problem than algebraic formulas, and indicate more readily the effect of changes in the quantities involved.

In the construction of Fig. 3B, it has been pointed out that the locus of points at which $P\,Q$ subtends a constant angle is a circle with centre R. But it may also be of interest to note that the locus of points the distances of which from A and B are in a fixed ratio is also a circle. If the line $A\,B$ is divided internally at N and externally at N' in the given ratio E_A/E_B, this circle has $N\,N'$ for its diameter.

In Appendix C the equation

$$\text{Power} = \frac{1}{2}\,(E\,I + E\,\bar{I})$$

is given. The truth of this equation may readily be seen from the accompanying diagram. Let $O\,A$ be standard phase, and

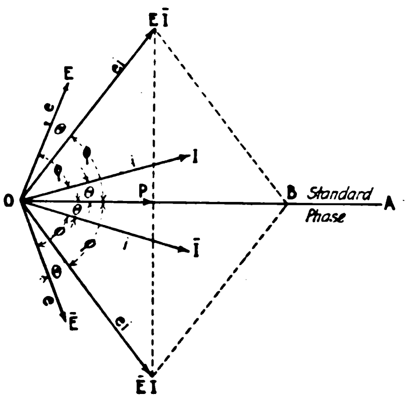

Fig. 9

let E and I be the voltage and current vectors the magnitudes of which are e and i. Then the conjugate vectors E and $\bar{I}$ will also have magnitudes of e and i, and their angles with $O\,A$ will be equal and opposite to those of E and I. To multiply the vector E by the vector I, we multiply their magnitudes and add (with due regard to sign) the angles they make with $O\,A$. The vector $E\,\bar{I}$ will therefore have a magnitude of $e\,i$ and will make an angle ϕ above $O\,A$, where ϕ is the angle between E and I. Similarly the vector $\bar{E}\,I$ will have a magnitude of $e\,i$ and make an angle ϕ below $O\,A$. Then clearly, the vector sum $\bar{E}\,I + E\,\bar{I}$ will be equal to $O\,B$, or $2\,e\,i\cos\phi$, which is twice the power in the circuit.

Sidney Withington (communicated after adjournment): Since the limit of power transmission is a function of the system frequency, it is entirely conceivable that in the transmission of large amounts of power over long distances it may be found desirable to adopt relatively lower frequencies than the standard 60 cycles; for instance 25 cycles or even lower. In this case there would be large frequency-changing substations at the centers of distribution. The frequency-changer sets might perform also the function of synchronous condensers, and the increment of cost would be relatively small compared to the total transmission line cost.

If this occurs and a low frequency is adopted for long distance transmission, it is entirely within the range of possibility that it would be economical for the electrified railroads of the country to obtain their power direct from these major transmission lines without the medium of rotary apparatus, perhaps balancing the load among the phases in sections. This is significant, considering the possibilities of railroad electrification, and may be a controlling factor in developing a standard system.

C. F. Wagner (communicated after adjournment): Miss Clarke has presented methods for the calculation of static stability for constant field current in a clear and concise manner. It should be noted in passing, however, that these limits do not represent the ultimate when automatic voltage regulators are used to maintain voltage. Miss Clarke uses the logical device of

Fig. 10

representing loads where possible by static networks. This results in considerable simplification.

Using the various devices pointed out by Miss Clarke, the most general case in which the problem can still be reduced to a single synchronous machine at each end is that shown in Fig. 9, herewith, in which the three rectangles represent general networks, E_a and E_d the internal voltages and b and c the points at which the voltages are known.

Messrs. Evans and Sels in the July 1921 number of the *Electric Journal* have indicated how three general networks in series can be combined into one equivalent, so that the following expression is obtained.

$$\check{e}_a = \check{A}_0\,\check{e}_d + \check{B}_0\,\check{I}_d \qquad (1)$$

where $\check{A}_0$ and $\check{B}_0$ are the general circuit constants for the three combined networks, $\check{e}_a$ and $\check{e}_d$ the star voltages at a and d respectively and $\check{I}_d$ the current at d.

Transposing equation (1)

$$\check{I}_d = \frac{1}{\check{B}_0}\,\check{e}_a - \frac{\check{A}_0}{\check{B}_0}\,\check{e}_d \qquad (2)$$

The power at d

$$P_d + j\,Q_d = 3\,\check{e}_d\,\hat{I}_d = \frac{1}{\hat{B}_0}\,\hat{E}_a\,\check{E}_d - \frac{\hat{A}_0}{\hat{B}_0}\,E_d^2 \qquad (3)$$

when E_a and E_d are phase volts at a and d respectively. Now let

$$\check{E}_d = E_d\,\epsilon^{j0} \text{ and } \check{E}_a = E_a\,\epsilon^{j\phi} \qquad (4)$$

$$P_d + j\,Q_d = \frac{1}{\hat{B}_0}\,E_d\,E_a\,^{-j\phi} - \frac{\hat{A}_0}{\hat{B}_0}\,E_d^2 \qquad (5)$$

The real component of the above expression P_d becomes a maximum when

$$\phi = \tan^{-1}\frac{b_0}{a_0}$$

where a_0 and b_0 are the components of $\check{B}_0 = a_0 + j\,b_0$. This determines the angle ϕ between a and d for which maximum power is delivered at d. It is necessary to calculate only the $\check{B}_0$ constant for the combined network.

$$\check{B}_0 = \check{A}_1\,(\check{B}_3\,\check{A}_2 + \check{D}_3\,\check{B}_2) + \check{B}_1\,(\check{B}_3\,\check{C}_2 + \check{D}_3\,\check{D}_2)$$

Having obtained the maximum over-all angle corresponding to maximum power delivered, the actual value of power delivered

can be determined by the following graphical means. From a knowledge of A_2, B_2, C_2, D_2 and the voltages at b and c, the sending and receiving-end power circle diagrams for the middle section can be drawn as shown by the heavy lines in Fig. 10. For any angle ϕ_2 between the voltages at b and c the power flow at these points is indicated by the points m and n. Every point such as m on the supply circle must also represent a point on a receiving circle for the first section. This latter circle is represented by the expression

$$P_b + j\,Q_b = \frac{1}{\hat{B}_1} E_a\,E_b\,\epsilon^{-j\phi_1} - \frac{\hat{A}_1}{\hat{B}_1} E_b^2$$

The center of this circle is located at $-\dfrac{\hat{A}_1}{\hat{B}_1} E_b^2$. It will be noted that all of these quantities are known and can be plotted at the point p. Now while the value of the voltage E_a is unknown (and incidentally will not be necessary to determine) the reference vector from which the angle ϕ_1 is measured can be drawn making an angle with the horizontal equal to that of $\dfrac{1}{\hat{B}_1}$ which angle is the same as the angle of $\check{B}_1$, *i. e.*, $\tan^{-1}\dfrac{b_1}{a_1}$ where $\check{B}_1 = a_1 + j\,b_1$. As stated previously, the point m must lie on the circle, therefore, and angle ϕ_1 between

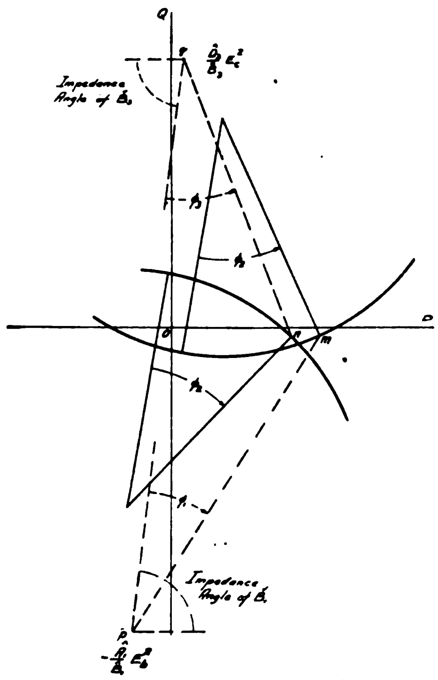

FIG. 11

$p\,m$ and the reference line indicates the angle between the voltages at a and b for the power transmitted at c corresponding to point n.

A similar construction applies to the receiving-end network. The power at c into this network is expressed

$$P_c + j\,Q_c = \frac{\hat{D}_3}{\hat{B}_3} E_c^2 - \frac{1}{\hat{B}_3} E_c\,E_d\,\epsilon^{+j\phi_3}$$

The center of the circle q is determined by $\dfrac{\hat{D}_3}{\hat{B}_3} E_c^2$ and the reference line makes an angle with the horizontal equal to that of $-\dfrac{1}{\hat{B}_3}$, *i. e.*, $\tan^{-1}\dfrac{b_3}{a_3}$ where $\check{B}_3 = a_3 + j\,b_3$.

The angle ϕ_3 between $n\,q$ and the reference line indicates the angle between the voltages at c and d. Therefore $\phi_1 + \phi_2 + \phi_3$ gives the total angle between the voltages at a and d for the power conditions at c corresponding to the point n. After a few

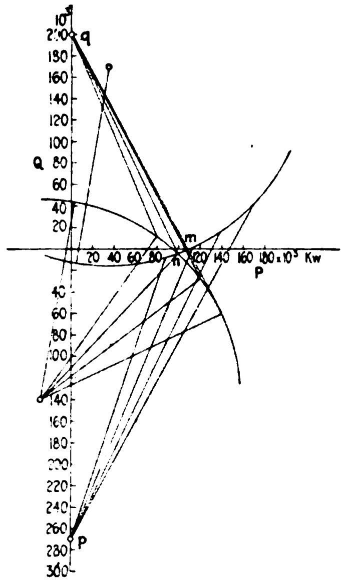

FIG. 12

trials the point n can be determined for which $\phi_1 + \phi_2 + \phi_3 = \phi$. This value of power indicates the maximum that can be transmitted at c.

The general method can best be illustrated by means of a solution of a particular case. The example chosen is that indicated on the eighth page of Miss Clarke's paper which involves the determination of the steady-state limit for a 270,000-kv-a. generator, transformers, a 250-mi. line and a 170,000- kv-a. synchronous motor. Complete details of line and machine characteristics are given on the sixth page of the paper. The voltage at the generator terminals will be maintained at an equivalent of 220 kv. and that at the receiving end at 200 kv. by hand regulation.

The combined constants for transformers and line are:

$$A_2 = 0.8431 + j\,0.0279$$
$$B_2 = 39.6 + j\,232.1$$
$$C_2 = (0.0104 + j\,1.248)\,10^{-3}$$
$$D_2 = 0.8428 + j\,0.0280$$

These constants enable one to construct the sending and receiving power circle diagrams in the ordinary way. These are indicated by the full lines in Fig. 11.

The center of the receiving circles for network 1 is located at $-\dfrac{\hat{A}_1}{\hat{B}_1} E_b^2$. Since this network contains only the generator reactance

$$\check{A}_1 = 1.0$$
$$\check{B}_1 = 0 + j\,X_1$$

and

$$\frac{\hat{A}_1}{\hat{B}_1} = \frac{1}{-j\,X_1}$$

$$-\frac{\hat{A}_1}{\hat{B}_1} E_b^2 = -j\,\frac{E_b^2}{X_1}$$

$$= -j\,\frac{220 \times 220{,}000}{179.2} = -j\,270{,}000 \text{ kv-a.}$$

Incidentally, this is equal to the sustained short circuit kv-a. at 220 kv. This point is indicated by the letter p on Fig. 3. The reference line coincides with the axis of reactive power.

The center of sending circles for network 3 is obtained in a similar manner.

$$\check{D}_3 = 1.0$$

$$\check{B}_3 = 0 + j\,X_3$$

$$\frac{\check{D}_3}{\check{B}_3} = \frac{1}{j\,X_3}$$

The center is located at

$$\frac{\check{D}_3}{\check{B}_3} E_c^2 = \frac{E_c^2}{-j\,X_3}$$

$$= j\,\frac{200 \times 200{,}000}{200} = j\,200{,}000$$

This point is plotted at q, the reference line being the axis of reactive power.

Now give ϕ_2 an arbitrary value, say 34 deg., and determine

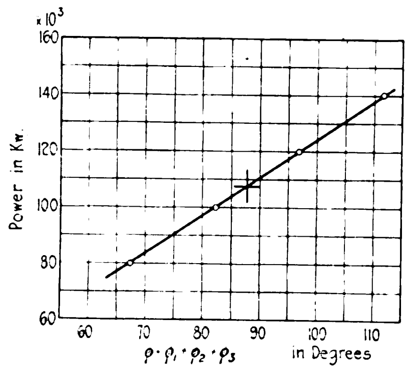

FIG. 13

m and n for this value. Draw $m\,p$ and $n\,q$ and measure ϕ_1 and ϕ_2.

$$\phi_1 = 22.3 \text{ deg.}$$

$$\phi_2 = 26.0 \text{ deg.}$$

$$\phi_1 + \phi_2 + \phi_3 = 82.3 \text{ deg.}$$

The total angle between internal voltages is then equal to 82.3 deg. for 100,000 kw. transmitted at receiving end. Choose a different value of ϕ_2 and repeat. By this means the curve shown in Fig. 4 can be obtained.

Substituting in the equation for B_0, this constant is found equal to

$$B_0 = 28.6 + j\,506.7$$

$$\phi = \tan^{-1}\frac{506.7}{28.6}$$

$$= 518.7$$

$$= 86.7$$

From Fig. 4 the maximum power, which occurs for $\phi = 86.7$ deg., is equal to 106,500 kw. which value checks the result obtained by Miss Clarke.

C. A. Nickle: There seems to be a misunderstanding of what the authors intended to convey by their use of the terms "steady-state power limit" and "transient-load power limit." To make this matter clearer, let us consider three cases of load change which may be classified as transient changes.

First, let us consider the change involved in throwing on a load. Before the load is thrown on, the line will have a certain voltage and the synchronous machines will have their magnetic circuits excited to give this voltage. Under this adjustment, the line will carry a definite maximum load of the type to be thrown on. What the authors intended to convey was that it makes very little difference in the ability of the system to carry the load whether this load is thrown on gradually or rapidly or even instantaneously.

Second, consider dropping a section of the line. We do not intend to say that the steady-state power limit to be used is that of the line before the section is dropped. The steady-state power limit to be used is the limit of the line with the section out and our tests again indicate that we can drop a section of a line which is carrying power so as to leave the remaining section with a load equal to its steady-state value and that this may be done gradually or quickly.

Third, consider the case of short circuits. In the case of three-phase short circuits, of course, no power can be transmitted beyond *the short circuit; that is, the final steady-state power has been reduced to zero*, and the load at that point will be dropped unless the relays relieve the condition very quickly. In the case of single-phase short circuits, the line has been weakened in its ability to carry steady-state power but the amount will be a definite value. If we take this same line with the short circuit permanently on and calculate its steady-state power limit,—that is, for loads slowly applied,—this will give the same value as when the short circuit is suddenly applied, the magnetic adjustment of the synchronous machines remaining unchanged.

It is very important that we choose the proper steady-state power limit. The reason single-phase short circuits are severe is because they reduce the value of the steady-state power which the system can carry. When we were able to carry 31 per cent of the steady-state power of the line before short circuit it meant that the steady-state value to be used was the value with short circuit on the line. If we increase the steady-state power limit by means of special excitation systems, such as mercury arc and other schemes, we also increase the transient power limit to the same value. In every case where we have tried this on the miniature system, we have been able to create any condition suddenly that we could produce slowly and still maintain synchronous operation.

Edith Clarke: Mr. Evans and Mr. Wagner have stated in their discussions that the methods used in my paper to obtain the maximum power which can be transmitted over a given transmission system under steady state are applicable for constant field currents and when the voltage is regulated by hand, but do not apply when there is an automatic voltage regulator on the system. Mr. Spencer has asked how the constant generator reactance, which is to be used in the calculations for maximum power, is selected.

In order to answer satisfactorily, it will be necessary to define constant field or fixed excitation and hand regulation and to explain what is meant by *equivalent* synchronous impedance.

For simplicity, assume a synchronous generator and motor on the same bus with constant and equal fields on both machines; then increase the load until the machines fall out of step, plotting power delivered *vs.* terminal voltage. If this is done for a number of different field currents, it will be noted that there is one curve in which maximum or breakdown power occurs at normal terminal voltage. On the curves corresponding to lower field currents, maximum power occurs at voltages below normal, while on curves corresponding to higher field currents, maximum power occurs at voltages above normal. With given fixed excitations maximum power will not in general occur at normal voltage. When hand regulation is used and load is slowly added so that normal voltage is maintained, the maximum power limit is usually understood to mean the power corresponding to that fixed excitation for which breakdown power occurs at normal terminal voltage.

It has been found by tests that with regulators such as are used commercially today, it is not possible to transmit more than the maximum power limit as defined above by hand regulation. I agree with Mr. Evans that if regulators were fast enough to maintain terminal voltage, the machine impedance could be

neglected; or if fast enough to maintain constant flux, then leakage reactance could be used; but until something is done to increase their speed of operation, the maximum power limit with voltage regulators will be the limit obtained by hand regulation.

Equivalent synchronous impedance is a fictitious value used for convenience to obtain maximum power. The field current corresponding to it is a fictitious current and does not represent actual field current. The justification for using *equivalent* synchronous impedance is that by its use the calculations have been greatly simplified and the calculated maximum power has been found to give a satisfactory check upon test values.

For a given machine, the sustained impedance which replaces leakage reactance and armature reaction is not constant, except for a machine of zero saturation, but varies with terminal voltage, power factor and load. The *equivalent* synchronous impedance likewise is not constant for a given machine but depends upon terminal voltage, power factor and load. In steady-state stability problems a voltage regulator is assumed; therefore maximum power is obtained at normal terminal voltage. The power factor on the generator for long lines heavily loaded is not far from unity. The load on the generator may be estimated after one approximation. Therefore, terminal voltage is known and power factor and load can be estimated.

When the leakage reactance, the armature reaction, and the saturation curve of a generator are given, the following *equivalent* synchronous impedance has been found to give a good approximation for maximum power.

$$\text{Equivalent synchronous impedance} = (\text{leakage reactance}) \text{ plus } \left(\text{armature reaction} \times \frac{\text{slope of saturation curve}}{\text{slope of air gap line}}\right).$$

The leakage reactance will be given in per cent values. The armature reaction should be expressed in per cent of the air-gap ampere-turns corresponding to no-load normal voltage. The slope of the saturation curve should be obtained at a point corresponding to virtual voltage. Virtual voltage depends upon terminal voltage, power factor and load, and may be estimated, but in general the slope of the saturation curve at normal terminal voltage may be used.

With voltage regulators or with hand regulation, the maximum or breakdown power will occur at normal terminal voltage so that the same value of *equivalent* synchronous impedance will be used and the same value for maximum power will be obtained in either case. With fixed excitations, however, the conditions are different since the voltage at which maximum power occurs is not given. The procedure is not so direct as where normal voltage is maintained but *equivalent* synchronous impedance may be estimated and maximum power obtained after one or two approximations.

R. D. Evans and C. F. Wagner: Mr. Sels makes a plea for a definition of stability limits, so that we may all know what the other fellow is talking about. We might refer to the definition as given in our paper in which we say that the stability may be defined as the capacity of a power system to remain in equilibrium under steady-load conditions and its ability to regain a state of equilibrium after a disturbance has taken place. The first part of the definition is referred to as static stability and the second part as transient stability.

Mr. Sels believes that the static limit is of the utmost importance. He believes that in the future it will be possible so to improve insulation that insulator failures will be very rare. We hope that such will be the case, but we are living in the present, not the future. For that reason, we believe that transient stability is of more importance at the present time than static stability.

Mr. Sels also stated that we have the stability problem present in all metropolitan systems. In general, however, the stability calculations for metropolitan systems are much more difficult and complicated than for long-distance transmission systems. In the latter the line constitutes the greater part of the impedance between the two points considered, the impedance of the terminal equipment acting more in the nature of a correction factor. In addition, generators at each end of the transmission line can be grouped together and considered as units. In metropolitan districts the connecting impedances are much more complicated and in most cases it is not permissible to simplify the problem by grouping the generators into two groups. The effect of faults and changes in voltages is more problematic.

The curve presented by Mr. Powel showing the relation between transmitted load and the probability of outage is both interesting and important. It would seem desirable to obtain similar data on the operation of other existing systems. Such data might be analyzed in a number of ways, one of which would be the plotting of the number of outages for different loads. Such a curve would take into account the load cycle under which the system is operated, and also the variation in the probability of failure during different parts of the day. Ater a considerable amount of data were available, it would be possible to plot curves for each of the various types of disturbances, such as low-tension faults, three-phase faults, and flashovers to ground; and from a study of these curves to determine the amount of consideration which should be given to each type of disturbance in making additions to existing systems, or in laying out new projects. In order to compare data on different systems, it would be desirable to plot the outage curve in terms of the angle between supply and receiver ends. This function would form the basis of comparison of operation of different systems. The collection of such system-operating data can best be obtained by the use of such recording instruments as described in the paper by Mr. Wilkins and in the discussion by Mr. Legg.

In connection with Mr. Doherty's discussion, we agree with him that the static limit is a more definite quantity than the transient limit. The point which we wish to emphasize is that system stability under disturbances is the more important problem and that the transient stability limit is the more important limit. We agree that with fixed excitation in machines, the maximum limit is quite a definite quantity. However, this limit is not the same as the limit of a system operating with voltage regulators for the case of slowly increasing loads. Under this condition of operation, the true static limit will be in excess of the limit determined by fixed excitation. This arises because of the phenomenon which, in our paper, is termed "artificial stability." It is stated in the paper by Nickle and Lawton, and is endorsed by Mr. Doherty, that the only function of the regulator is to increase automatically the excitation as the load is applied, the actual limit being the same as that for hand control. Our paper presents results of analytical work on this problem which indicate that a condition of artificial stability in which the system is held together merely by the action of regulators, is possible. Since this paper was written, these results have been verified by experiments. The set-up consisted of a d-c. motor, a-c. generator, artificial line, an a-c. synchronous motor, and a d-c. generator loaded on resistors. With hand regulation, increasing the excitation to maintain constant terminal voltage as the load was slowly applied produced a limit of 65.1 kw., and with voltage regulators 79.6 kw., an increase of some 20 per cent. Mr. Doherty states that tests which he has carried out have not shown the existence of stable operation for loads beyond the static limit determined by hand control. He does not deny the possibility of such operation, but merely states that he has not found such a condition. It is possible that this disagreement may be ascribed to differences in the mechanical inertia and in the time constants of machines, particularly of exciters.

While we point out that this additional limit is available, we do not wish to imply that we advise working to this limit in ordinary operation. It should be recognized that this limit is available, and that advantage could be taken of it for emer-

gency operation. This matter of artificial stability, however, is largely one of academic interest. We do not wish to emphasize it too strongly. The real limit of practical importance which we have pointed out, and have tried to emphasize, is the transient limit. It is gratifying to find that the tests of Messrs. Nickle and Lawton on miniature systems bear out this contention.

Prof. Dwight has called attention to the difference in the method of plotting reactive kv-a. in power-circle diagrams. In the absence of an A. I. E. E. standard governing this practise, the various investigators have used the convention that seemed to them most logical and convenient. We heartily endorse Prof. Dwight's plea for A. I. E. E. standardization ruling on this point.

Mr. Barfoed brings up the matter of line insulation and circuit-breaker performance for 220-kv. systems, as affecting the general stability problem. In addition, Mr. Wilkins has called attention to the fact that 220-kv. circuit breakers may have a small time lag between the opening of the three poles. This difference in time in the test described by Mr. Wilkins was due to the failure to secure simultaneous mechanical opening of the three poles of the circuit-breaker. This is evidenced by the fact that the time required for opening the breaker was closely the same and independent of the load carried in the various tests. The oscillograph records also showed the time of arcing was approximately the same on the three poles, and could not be responsible for the period of about 0.2 seconds from the beginning of arcing on the first pole to the final interruption of the circuit. The 220-kv. circuit breakers can be adjusted to open the contacts on the several poles in about a cycle, as measured by the cycle counter. Furthermore, it may be pointed out that in the new breakers for 220-kv. service, further improvements have been made which secure more positive action, and facilitate adjustment in the field. Tests of a type similar to that described in the paper have been made subsequently, and in these it was found that the difference in time of operation at the three poles was less than two cycles.

Mr. Withington has called attention to the fact that the power limits at 25 cycles are considerably higher than at 60 cycles. This is a pertinent point in connection with the selection of the frequency to be used for railway electrification and general power purposes.

Mr. Roy Wilkins: It might be worthwhile to give the actual operating experience to reassure those who contemplate building such lines that they can be operated. One line has been in operation for twenty-two months and the other about nine months. There have been twenty-six total cases of trouble, of which two were mechanical, four were caused by birds (which was definitely known since the birds were killed), two by lightning, and five were located but the cause not known. The remainder have never been located. Four of these interruptions, of which two were mechanical and two caused by lightning, caused interruptions of one line of longer than three minutes. The balance were momentary line interruptions and the line went back without any change whatever. These lines are normally charged from the generating plant at reduced frequency, usually thirty-five cycles, in which they build up with the field circuit open, to the normal voltage and little above normal current. The condenser is then put on at the receiving end and they are brought up to full frequency and paralleled at the receiving end. Thereafter the load is pulled up and they are paralleled at the sending end. Customarily, this is carried out without any dispatching whatever, and the whole procedure has been carried out in approximately one minute. In times of great stress, for instance, if one line goes out over the peak when the load is high, we charge the full 202 miles back to the system and parallel at the power house. This gives a voltage rise at the substation end of 10 per cent and is not customarily carried out.

The two lines, by the ordinary method of analysis, will carry about 198,000 kw. each. We plan never to run over 120,000 kw. on them. At such time that the load increases above this point, segregating points will be added in the line. When development requires, there will be four complete lines.

The question has been brought up about the oscillographic wattmeter and meters. This oscillographic wattmeter is more or less of a novelty. It is felt that it is reasonably accurate. It requires so little power that the ordinary bushing-type transformer will supply it without serious error in ratio and it will record disturbances lasting as short a time as about $^1/_{20}$ sec.

DIELECTRIC ABSORPTION AND THEORIES OF DIELECTRIC BEHAVIOR[1]

(WHITEHEAD)

AND

THEORY OF ABSORPTION IN SOLID DIELECTRICS[2]

(KARAPETOFF)

NEW YORK, N. Y., FEBRUARY 8, 1926

A. E. Kennelly: In Faraday's time, the properties of substances under magnetic stress or magnetization, and the properties of dielectric materials under dielectric stress or electric induction, were studied and were regarded as of great interest by him and by his followers.

It seems remarkable that, using the relatively feeble magnetic stresses and magnetic fluxes of ordinary dynamoelectric machinery according to Ewing's theory, it is not necessary to go deeper perhaps than the molecules of the iron or steel in order to account for the main features of magnetic induction. No doubt when we come to consider much more powerful magnetic stresses such as in the Zeeman effect it may be necessary to go deeper than merely into the molecule, or into groups of molecules. On the other hand, however, in order to account for the behavior of dielectric material under electric stresses, it seems that even with the relatively feeble stresses of electric signalling, a consideration of groups of molecules or even of molecules themselves is inadequate, and it seems necessary to descend to the subatomic state to explain the phenomena.

Strange to say, in the early history of electrical engineering, going back to the time when the only electrical engineers were the telegraph engineers, the study of dielectric absorption was found necessary for practical purposes, in order to specify the insulation resistance of a given length of any kind of solid insulated conductor. It was necessary as our textbooks show, as far back as the 1850s, to take some account of dielectric absorption, and it was known that the apparent insulation resistance at the beginning of the first quarter-minute was different from what would be obtained at the first half-minute or at the first minute. It became necessary, I think, in the 1860's, to define the measured insulation as that obtainable at a certain definite interval of time, let us say one minute or three minutes after the application of the continuous dielectric stress.

W. A. Del Mar: I have run into the same difficulty that Professor Whitehead mentioned; namely, that the physicists who are working on the theory of electrons and the ultimate nature of matter have not reached a stage of progress in their work where they can help us very materially in our theories of absorption in electric strength, and I don't believe that very great progress will be made until the physicists who are dealing in those ultimate matters make some further steps forward.

A few years ago I would have thought that the experimental physicists and those who are dealing with such matters as electric strength and absorption were the ones who would have to take the principal steps in order to reach a rational theory of the behavior of dielectric, but I have now come to the view that the pure scientists are the ones upon whom we are waiting.

We must be careful, in studying such a subject as dielectric

1. A. I. E. E. JOURNAL, June 1926, p. 515.
2. A. I. E. E. JOURNAL, March, 1926, p. 236.

loss and power factor, not to put a word in place of a phenomenon and take refuge behind the word. There is a little danger that we may do that with the word "absorption". It is taken to cover a multitude of sins, and when one reads through Professor Whitehead's admirable summary, one has to stop occasionally and think: What is the meaning of this "absorption?" Is it not just a word which is being used in a general way to cover a great variety of phenomena?

One might perhaps get the impression, by reading Professor Whitehead's summary, that there are several theories which might be chosen from, to explain the phenomenon, whereas more likely all of these theories will be required in some measure to explain it in full.

R. E. Marbury: Dr. Whitehead has given us a very complete review and valuable bibliography of what has been done on dielectric absorption and related phenomena.

Our experience has indicated that Maxwell's theory can explain dielectric absorption and a-c. losses of the low frequency type. Maxwell's theory assumes that the s. i. c. and resistivity of the dielectric remain fixed. This is generally the case in solids, but with semi-liquid dielectrics, such as oil-impregnated paper, there is evidence of changes in either s. i. c., resistivity, or both, with voltage, or temperature. This may be illustrated by plotting the residual voltage under a fixed set of conditions, against various applied voltages. If the law of superposition holds and if the resistivity and s. i. c. remained fixed throughout, a straight line relation would be found. This is not the case, as we find that the residual does not increase proportional to voltage. In some specimens the applied voltage may be doubled with little effect on the residual. The conditions may be changed so as to modify this relation. For example, if the duration of charge is made very small, such as 0.0015 sec., the resulting curve may be a straight line and appear to follow the law of superposition. This, among other things, leads us to believe that this departure from the law of superposition is caused by a movement of moisture, and when the duration of charge is made too quick for the moisture, the dielectric acts like a solid, as is to be expected.

A dielectric which shows this non-proportional residual possesses other interesting characteristics. For example, the losses will decrease with increased voltage. Such a dielectric will show a marked decrease in losses with time after the application of voltage. The latter effect may be seen by measuring the losses at five-sec. intervals, starting five sec. after the voltage is applied.

It is now possible to predict quite definitely certain characteristics of a condenser from absorption tests of the proper type. These characteristics are:

1. Whether the losses will decrease or remain constant with voltage.
2. How the capacity will vary with frequency.
3. Completeness of drying process.
4. Magnitude of loss variation with temperature.
5. Whether the condenser will give good performance on alternating current.
6. Whether the condenser has characteristics desirable for d-c. operation.

We can predict less accurately the actual losses, and can calculate a curve which will have a shape closely following the real curve which will be found if losses are plotted against voltage.

It appears that a complete interpretation of absorption curves will make possible a closer control of dielectric characteristics than has heretofore been possible.

R. W. Atkinson: I wish to remark that great increase in our knowledge of dielectric phenomena is certain to be made in the next few years on account of the interest and attention given these problems by the leading physicists in the faculties of the colleges and universities of this country. The present and other recent contributions are an important part of the recent advance, especially as leading toward a clearer understanding of dielectric phenomena.

When Mr. Fisher, for our company, first began measuring dielectric losses, before I was associated with him and also during the early part of my work, we found it useful to measure both quantities, dielectric absorption and dielectric loss, and a very close relation between them was observed, and for a long time both measurements were faithfully made on all materials.

Later, the large increase in the number of dielectric loss measurements necessitated that attention should be concentrated on the loss end of the problem. But I believe it is important to have further investigation of the absorption side, and have no doubt it will lead to valuable knowledge of the subject.

I believe that the greater part of the losses in paper cable dielectrics at high temperature can be quite largely accounted for by specific numerical application of Maxwell's method.

E. S. Lee: If you will look into the bibliography which Dr. Whitehead has prepared, you will find some three hundred and fifty items, and yet we have the work of Tank—one man—given to us as "apparently the only effort so far made for a direct check between measured loss and loss computed from measured absorption."

I think that is a condition about which we ought to think and I think that it is largely because of that condition that Professor Karapetoff worked out a formula which we could use in this regard. In other words, if, for any insulation we shall determine the curve of current against time and determine it well,—that is, allow the insulation to retain its initial condition between each measurement and obtain the curve with which we are familiar and then obtain the constants M and N, which you will find in Professor Karapetoff's paper, from that curve,—then the dielectric power loss of the insulation may be calculated from the equations given. This value may then be compared with measured values, and we shall be able to determine whether or not the equations which Professor Karapetoff has derived are applicable to the work which we have at hand.

We have tried to do this, somewhat, and have found, thus far, that out of 13 articles in the literature, only one had data which we could substitute in these equations.

So I make a plea to those of us who are interested enough to obtain data, that we shall obtain it in such a manner that we may make proper substitutions into the formula which Professor Karapetoff has derived in order to determine whether or not it applies. When you consider all of the work that Dr. Whitehead and his Committee have done, and when you find the meager amount of data that is available for substitution directly into such formulas as we have, it seems as though we had overlooked something in connection with the work, which should be rectified in the future.

D. W. Roper: Dr. Kennelly, I believe, stated that our knowledge of this subject was far from complete.

And Mr. Lee apparently has somewhat the same idea, because, after a careful study of the paper, he picks out one sentence which sums up the knowledge that he was able to use on the subject.

Now, if there is all that difficulty in getting some real knowledge about the very simplest forms of insulation, how much more difficult and how much more remote is the chance of our getting some fundamental knowledge regarding such a very complex insulation as impregnated paper, such as is used in our lead-covered cables. Dr. Whitehead touches upon that point a little in his final paragraph.

I have been endeavoring, with a very great effort, to find some method of measuring the quality of the insulation without destroying the insulation, and apparently there is no such method. We don't know enough about insulation to measure the quality, without destroying it, and so what we do in practise is to measure the quality of some samples of insulation and then include in our cable or our machinery some insulation which is similar

to the samples we have tested; and we hope that the insulation which we use will be just as good as the samples. Until we can get more fundamental knowledge of the properties of the insulation, we shall not be able to replace that hope with knowledge.

J. Slepian: Equation No. (**10**) in Dr. Whitehead's paper and No. (**21**) in Professor Karapetoff's, written with a little different notation

$$D = K_o E + \int_0^t E(u)\,\phi(t-u)\,d\,u \qquad (1)$$

is a very interesting one and gives a complete account of the electrical behavior of a dielectric in those cases in which it applies. Professor Karapetoff has called the function ϕ a relaxation function. Another viewpoint is to call the function a memory function, as this function indicates how much the dielectric remembers of the voltage which has been impressed upon it in the past. As will be seen in Fig. 1, if $E\,(u)$ represents the voltage gradient which has been applied to the dielectric from the time $u = 0$, then at the time $u = t$ the displacement of the dielectric according to the above equation depends not only upon the value of E at the time $u = t$ but on all the preceding values. However, the preceding values are not taken with equal weight but are multiplied by a factor which diminishes as the time recedes further into the past. The function $\phi\,(t - u)$ represents this weighing factor. In other words, it shows how the dielectric has a diminishing recollection of past voltages.

The equation (**1**) follows directly from the principle of superposition, as both Professor Karapetoff and Professor Whitehead

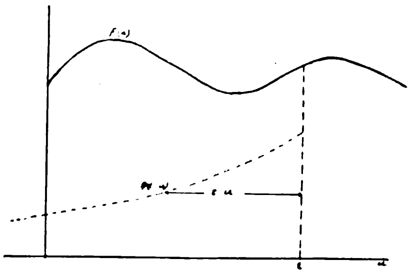

Fig. 1

bring out. It is also true that solutions of linear differential equations with constant coefficients can always be expressed in the form of equation (**1**). The simplest memory function is probably that which corresponds to a first order linear differential equation and that is a simple exponential. The memory functions of higher order differential equations are made up of sums of exponential functions. If a number of electrical systems, each satisfying a first order linear differential equation and therefore having a simple exponential memory function, are coupled together in any way, the resulting system is characterized by a linear differential equation of high order, with a more complicated memory function. Likewise a given system with a complex memory function is equivalent in its action to a large number of simple systems coupled together.

The resolution of the complicated system into simple systems is quite indeterminate and can be effected in a variety of ways. Referring specifically to the problem of the dielectric, it has been attempted to resolve the dielectric with complex memory function into an aggregate of dielectrics with simple memory functions, but such resolutions are indeterminate and usually of little value unless properties other than checking ordinary electrical measurements are considered. Maxwell, Wagner, and others suppose the dielectric made up of an assemblage of materials, each having a simple dielectric constant and ohmic resistivity. Karapetoff makes the dielectric consist of an aggregate of small pieces of dielectric, each piece having a simple memory function, without explaining how it comes to have that property. Von Schweidler assumes various kinds of molecules each with its own memory function combining to give a more complex memory function to the dielectric.

All of these theories lead to the same result,—namely, the equation (**1**)—and say no more than that the principle of superposition applies to the dielectric. Maxwell & Wagner's theories will have value only in those cases in which portions of the dielectric can actually be found which have simple dielectric constant and ohmic conductivity. Karapetoff's theory likewise will have value only if he can actually determine by means independent of the ordinary electrical measurements, the existence of portions of dielectric having simple memory functions. Von Schweidler too must show independent evidence of the existence of his various kinds of molecules. All these theories are sufficient to account for the principle of superposition. None of them is necessary. It seems to be a choice of being satisfied with the idea of the homogeneous substance having complex dielectric properties or a complex assemblage of materials having simple dielectric properties. Unless, however, there is physical evidence of some kind for the existence of the complex assemblage of simple substances, I do not believe that anything is gained over the assumption of the homogeneous substance with complex characteristics. As far as agreeing with electrical measurements, all these theories are on a par, provided they accurately represent the memory function of the dielectric.

That these theories without other physical evidence do not add to our knowledge of the dielectric seems to be intimated by Professor Whitehead when on page 11 he says of Von Schweidler's theory "The analysis has the character of a mathematical fiction," and again further along on the same page, in speaking of the check which Grover made upon the Pellat theory, "It appears certain that an equally good agreement would have been obtained from Wagner's equations; in fact it is safe to say the same of any theory providing for the medium a sufficient number of terms, all obeying a continually decreasing function $\phi\,(t)$ of relatively simple form but with different values of the constant terms."

While it is true that a heterogeneous assemblage of simple dielectrics will show absorption and satisfy the principal superposition, it does not follow that a material showing absorption is necessarily heterogeneous, and to my mind the physical evidence on that point is far from conclusive. Very pure substances show little absorption, but, at the same time, they usually show a tremendously high resistance. When two pure substances are mixed they frequently show absorption, but such mixtures are hardly to be described as heterogeneous and the absorption which arises frequently is not consistent with the numerical values of the dielectric constant and resistivity of the pure materials themselves. For example, a mixture of pure water and pure sulphuric acid shows a great conductivity which cannot be accounted for on the theory that it is a heterogeneous assemblage of the pure substances, each of which has a tremendously high resistance.

How universal is the principle of superposition for dielectrics? The existence of the irreversible current which Dr. Whitehead points out shows at once that it does not always apply. Last year Mr. Marbury, in his paper on oil condensers, showed phenomena which contradicted the principle of superposition. The departure from the law of superposition may take place in various ways. First the memory function may change with time of application of voltage as, for example, when water in the pores of a material is displaced gradually by the electric field. The memory function may change with amplitude of voltage as it undoubtedly does near the dielectric breakdown point of the material, or finally the properties of the material may not be characterizable by a memory or relaxation function at all.

The paragraphs of Professor Whitehead on electric hysteresis, I think, are exceedingly good and to the point. The phenomena of dielectric absorption and magnetic hysteresis are too unlike in character to be confused by a similar name. In the language

of my preceding discussion, whereas a dielectric has memory of past electric fields which diminishes with lapse of time, a piece of iron has an unchanging memory of the fields which have acted upon it. You may put a piece of iron through magnetic cycles today and tomorrow the iron will be ready to go on from where it left off, no effect of the magnetic fields of the previous day being lost.

The work of Debye and Schrodinger, I believe, deserves more than the casual mention which Professor Whitehead gives. Their polarized molecules have an actual physical reality, since, in their work on dielectric constants of gases, they are able to explain the dielectric properties by assuming that all the molecules of the gas are polarized with moments of the order of magnitude consistent with other phenomena and are able to predict correctly the effect of temperature by calculations from the kinetic theory of gases; thus Debye and Schrodinger give a complete theory of the dielectric properties of an un-ionized gas, the only case in which such complete theory has been given.

I wish to take issue with Professor Whitehead with respect to what he calls the fundamental equations of electromagnetism. In his classification on page 7 he implies that some of the theories given involve deviations from the fundamental laws. I believe the common usage is to regard the following equations as given by Maxwell fundamental:

$$\text{Curl } E = -\frac{d^B}{d\,t} \tag{1}$$

$$\text{Curl } H = 4\,\pi \frac{d\,D}{d\,t} + 4\;C\,\pi \tag{2}$$

$$\text{Div. } B = 0 \tag{3}$$

$$\text{Div. } D = -\,4\,\pi\,\zeta \tag{4}$$

These equations correspond respectively, the first to Faraday's law of induction, the second to the manner in which conduction and displacement currents give rise to magnetic fields. The third equation states the fact that free magnetic charge does not exist, and the fourth, that lines of electric flux terminate in electric charge. These four equations are not sufficient to determine the quantities E, H, B and D, but further relations must be found connecting B and H and D and E, depending upon the properties of the material considered. In the simplest theories, it is customary to take $B = \omega\,H$ and $D = \epsilon\,E$. These last equations are the ones which are not adopted by some of the theories which Professor Whitehead mentions. However, they are not fundamental in electromagnetism; they are only a very special case in electromagnetism.

C. A. Adams: As I was originally responsible for the organization of the Insulation Committee, of which Dr. Whitehead's excellent paper is a one-man report, I am naturally interested in its progress.

But the attack which I had in mind was a very much more vigorous one that is now being conducted largely by voluntary services.

A more thorough understanding of dielectric phenomena in solid and semi-solid dielectrics constitutes the most important problem in the whole field of electrical engineering at this time. But unfortunately it is a terrifically complicated and difficult problem from the standpoint of modern theory. It has been almost completely ignored or shirked by our American physicists, and the very suggestive and interesting first steps taken by two or three foreign physicists are buried in the proceedings of the more highly scientific organizations.

This most important problem is not going to be solved by engineers. We need a comprehensive fundamental research involving the cooperation of the best physicists and chemists that the world affords, and backed financially by the great corporations who either manufacture or use insulating material.

The cost to any individual corporation would be small, if they all took part, particularly if the cooperation were extended to other countries, as it should be in a problem of such fundamental scientific and commercial importance.

Much research work in this field is now being conducted in this country, but mostly by engineers, who, owing to lack of thorough knowledge of modern theory, are only skimming the surface. Moreover, there is no thorough cooperation, and much duplication of effort.

If the A. I. E. E. wishes to stand for cooperation and progress, here is certainly a supreme opportunity.

S. L. Gokhale: I have nothing to contribute directly to the topic under discussion; my purpose is merely to supplement the very suggestive remarks of Dr. Kennelly by an interesting experiment of ours in the General Engineering Laboratory.

Dr. Kennelly has suggested that the dielectric phenomena are perhaps sub-atomic in their nature; he also referred to the magnetic phenomena as being analogous to the dielectric phenomena, so that any insight into the one phenomenon might help to give us a better understanding of the other. The experiment I am going to describe refers to magnetics, and I am describing it in the hope that it may prove of use to those who are trying to study corresponding phenomena in dielectrics.

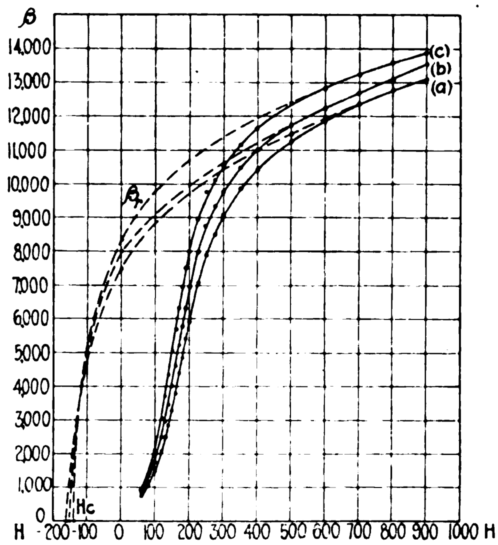

FIG. 2—COBALT MAGNET STEEL (SAMPLE NO. 16-1) CHANGE OF MAGNETIC CHARACTERISTICS APPARENTLY DUE TO STRONG MAGNETIZING FORCE

The sample under test was a toroid ring sample of cobalt magnet steel, wound for a magnetizing force of about $H = 1000\,g$. The resulting curves are shown in Table I. The curve (a) is the result of the first test; the point for $H = 900$ gave at first $\beta = 13{,}000$, but the reading could not be repeated on second and subsequent tests, and on going back it was found that other points could not be duplicated also. The whole test was therefore repeated, and gave the curve (b). At $H = 900$, the curve developed the same anomaly as before. The whole test was therefore repeated once more, which gave the curve (c). A fourth test gave a further shift of about 50 gausses with a corresponding increase of deflection of half a millimeter. The sample seems to have reached a steady state now. The hysteresis curve (dotted) is conjectural, but the cardinal points $\beta\,r$ and H_c are observation points. It seems that during the test the sample was softening, probably under the influence of the strong magnetizing force. It was probably not a heat effect, as the precaution against heating had been tried out in some previous tests, and was found to be quite satisfactory; no thermic measurements were made in this particular case.

In trying to interpret the phenomenon, my first guess was that there was some change in the structure of the molecular

systems which are supposed to be oriented during magnetization. This explanation implies a modification of Weber's theory, which refers to orientation of the molecules. On trying to discuss the question with my colleagues in the Research Laboratory, I was informed that in view of the recent researches about the structure of the crystals, as revealed by the X-Ray spectroscope, there is no intermediate step between an atom of iron and a complete crystal. The phenomenon of magnetism should therefore be regarded as an atomic or sub-atomic phenomenon, which leaves no room for Weber's theory of molecular orientation, and even less room for my theory of molecule-system orientation.

I do not claim to have understood the phenomenon; I am not even convinced that it is sub-atomic. I am mentioning it here in the hope that it might help in some way towards a better understanding of the process of magnetic polarization in the first place, and of dielectric polarization by analogy.

J. B. Whitehead: All writers on the theory of dielectric absorption have discussed the form of the curves of current of residual charge and discharge. A number of these are set forth in my present paper. All such workers have recognized that a single term of any of the forms mentioned will rarely represent the experimental curve. Hopkinson found for his samples that two terms were not enough, and Maxwell gave general expressions for n terms as required in a mixture of $n + 1$ materials. A number of observers have found that for some simple substances one term is closely sufficient.

Professor Karapetoff's paper is based on the assumption that a great many, perhaps an infinite number, of such terms are necessary. The Germans, Wagner and Von Schweidler, have also made this assumption and have attempted analytical developments which should in effect permit us to assign definite constants to particular materials which would fit the relative importance of this large number of terms and so define the behavior of the material. Professor Karapetoff has gone somewhat further, first in selecting a function fixing the distribution of the series of terms which is somewhat easier to handle, second in allowing us to follow more intimately his ingenious mathematical manipulation, and particularly in evaluating the changes which may be looked for under alternating voltage, in the values of conductivity and permittivity as affected by his "generalized absorption."

But while we may admire the persistence and skill manifested in these developments, I question seriously whether they constitute the necessary path by which we will ultimately reach a position in which we can control and predict the performance of dielectrics for the following reasons:

It has never been shown that $\phi\ (t)$ is uniform or the same for any given material. Why discuss $F\ (\alpha)$ if it may have widely different forms for the same material prepared in different places? The absorption of any material may be continually reduced by greater and greater care in purification. Hopkinson showed that while two terms were not sufficient to account for his curves, not many more would be required. Steinmetz showed that even in so highly absorbent a dielectric as cable insulation, three terms were sufficient to very closely account for the observed curve. There are many instances where one term appears sufficient. F. Tank has studied $\phi\ (t)$ for very small values of t, has found it of simple form, *i. e.*, one term, and that the use of a single term in developing the expression for loss under alternating voltage gives values in accord with experiment.

Professor Karapetoff states that the time for a rational theory of dielectric absorption has not arrived. One must ascribe this statement to momentary forgetfulness, induced by deep interest in the theory of Pellat, and his elaborate development thereof. I am sure that he will agree with me that Maxwell's theory of dielectric absorption, relying as it does only on fundamental electromagnetic theory, and in no wise invoking the structure of the atom, is in every respect a rational theory. Maxwell, as everyone knows, explains dielectric absorption entirely in terms of the specific conductivities and specific inductive capacities of

different substances when mixed together. It accounts qualitatively at least for most of the important phenomena to be observed in the dielectrics of practise, and does this quite as satisfactorily as any other theory. If it is not subject to exact experimental corroboration, it has certainly never been shown that this is not due to the impossibility of obtaining strictly pure and simple materials or mixtures. Maxwell himself recognized the probability of this difficulty and extended his expressions so as to embrace any number of different materials. Followers of his theory have always assumed that the several terms often needed to account for the shape of the curves of charge and discharge, are due to the presence of other substances or impurities throughout the mass of the principal dielectric. Wagner is a follower of Maxwell, and in his development of the distribution function he has attempted to picture the type and method of mixture of the conducting impurities in the mass of the dielectric. If this view is correct, and there seems to be no satisfactory contradiction of it, it would appear that the evaluation of distribution functions such as assumed by Von Schweidler and Wagner, and now by Professor Karapetoff, resolves itself into an effort to define the particular ways in which impurities may occur in a fundamental material. Obviously there is no reason to suppose that on this basis the distribution function can ever be the same in any two cases, even for the same fundamental material.

These questions have long excited the discussion of those interested in the theory of dielectric theory and behavior. The following are a few experimental problems the solution of which would go far toward solution of some of the open questions:

To fix the definite curves of particular substances, and the accuracy with which they can be reproduced.

To determine the importance of their departures from simple curves.

To study the control of these curves.

To study their behavior in combination in different substances.

To study the relation between absorption and loss for some of the simpler cases.

In my opinion careful work in these directions will be found to greatly simplify the present confusion as to the nature and behavior of dielectric absorption, and further will result in enormous simplification of the problem of engineering design and insulating mediums.

H. L. Curtis (by letter): Dr. Whitehead has reviewed a large amount of literature and has made an excellent summary of our present knowledge of the anomalous behavior of dielectrics. It is a fair and impartial discussion of all the theories that have been proposed to explain this most baffling phenomenon. It should serve as a starting point in the extension of our knowledge of dielectrics.

I agree with the author that, from a theoretical standpoint, the most satisfactory theory of dielectric absorption is that of Maxwell's stratified dielectric. However, I do not agree that there is any chance that it can explain all the observed facts. One illustration will suffice. The application to alternating current phenomena of Maxwell's theory or any of the modifications proposed by Rowland, Wagner, and others, invariably leads to an equation for the phase difference which is equivalent to equation (**31**). For high frequencies, this equation takes the approximate form

$$\tan \delta = \frac{k}{\omega T}$$

so that for such frequencies the phase difference is inversely proportional to the frequency. Now there are abundant data to show that this is not the case in many dielectrics. Hence in such dielectrics it appears impossible to explain the phenomena on the basis of this theory.

However, there are other dielectrics where the observed phenomena are largely explainable by Maxwell's theory. Moreover from the fundamental assumptions of this theory it must play some part, however small, in most absorption phenomena, since homogeneous dielectrics are extremely rare. The conclusion must therefore be drawn that the final explanation of dielectric absorption will include at least two theories of which Maxwell's stratified dielectric will be one.

Professor Karapetoff has given a very clear derivation of the integral equation (Eq. No. **21**) which results when the principle of superposition is applied to an absorbing dielectric in an alternating electric field. Wagner's relaxation function (Eq. **25**) is then inserted in this integral equation and the solution carried to a point where both the change of capacitance with frequency and the power factor are expressed in terms of integrals which involve both the relaxation function and the frequency. An empirical expression (Eq. **56**) for the relaxation function is then assumed and the integrals evaluated. The results (Eqs. **103** and **104**) are given in terms of ascending powers of the frequency. There is, however, no discussion of the convergence of these series. It is evident that, for high frequencies, they either diverge or become impracticable as methods of representing the function.

The value of the paper would have been greatly increased had it contained some numerical examples. At best the results as given are applicable only to low frequencies. Whether this includes frequencies that are of any practical or theoretical value can not be judged from the equations as given. Until the paper is completed by the application of the equations to typical sets of data, one should withhold judgment as to the value of the results obtained.

J. Katzman: Professor Whitehead's paper reviewing and bringing together the many theories of dielectric absorption and indicating the behavior of dielectrics under various conditions as found by former experimenters is certainly of inestimable value to all those engaged in this work. However, the divergence of views, theories, and results obtained makes it impossible, as yet, to predict effects from given causes. Qualitatively predictions can more readily be made, provided the knowledge of accumulated facts is had. Effect of temperature may be prophesied if it is known and remembered that according to Hopkinson and others, absorption current increases with temperature, and that according to Wagner, rate of absorption and decay is increased with temperature and the total absorbed charge remains unaltered. From Lahousse's equations it may be surmised that a loss in a dielectric will vary as the square of the voltage. Similarly, effects of frequency on loss per cycle, on loss per minute, and on capacity, and the effect of voltage

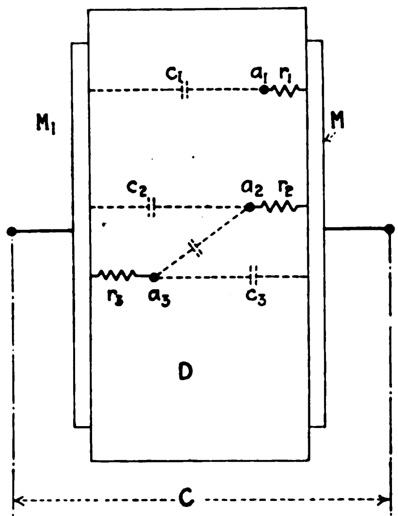

FIG. 3

on absorbed charge, etc., may be foretold if results of former experiments are remembered, or resorted to.

To be able to say, even approximately, what may be expected when a dielectric is made to undergo a change, is often of great value, and this may be deduced from a consideration of the properties of conductors and specific inductive capacity only. Assume the dielectric to have conducting particles embedded in it and the dielectric itself to have conductivity. Fig. 3 is a diagram of a condenser having a dielectric D, the metallic plates M_1, M_2 on the opposite faces of the dielectric, and some of the conducting particles a_1, a_2, a_3; r_1, r_2, r_3 are the resistance of the dielectric between respective plates and particles as shown. Each of the particles will form a sub-condenser with one of the plates or with each other as indicated. By forming a mental picture of such a condenser, all of the facts mentioned before concerning dielectrics can be reasoned out. Thus when the applied e. m. f. is altered, the charging current of each of these sub-condensers is proportionally altered and therefore $I_3^2\, r_1$, $I_1^2\, r_1$, etc., varies as the square of the voltage. The summation of these losses being assumed to produce the absorption loss, it is seen that absorption loss will vary as the square of the applied e. m. f.

With but very few exceptions when temperature is increased

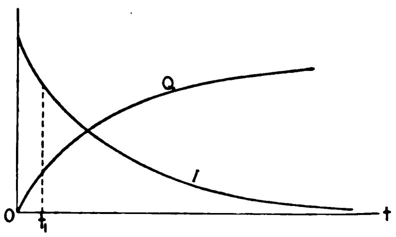

FIG. 4—CURVES OF VARIATION OF CHARGE AND CHARGING CURRENT WITH TIME

the resistivity of solid insulators reduces.[1] Hence resistances r_1, r_2, etc. reduce. The effect is therefore to reduce the time constants $c_1\, r_1$, $c_2\, r_2$, etc. of the sub-condensers, thus increasing the rate of absorption and decay, but does not alter the total absorbed charge, in accordance with Wagner's conclusions. The absorption current having increased, $I_1^2\, r_1$, etc. increases even though r_1 does decrease. The result to be expected then is an increase in power loss due to absorption.

When the frequency is increased the time available for charging the sub-condenser is decreased, and as can be seen from Fig. 4, if this time is t_1, the condensers will be only partially charged, with the result that absorption loss per cycle is decreased since the loss per cycle is $\int_0^{t_1} I^2\, r\, d\, t$. From the shape of curve I, it is obvious that the greatest loss occurs only at the beginning and therefore the reduction in loss is less in proportion as the frequency is increased. It follows then that the loss per second is increased by an increase of frequency. It is readily conceivable that the sub-condensers increase the capacity C by increasing the ratio Q/E, where Q is the total charge and E the applied e. m. f. At very high frequencies, however, the charge on the sub-condensers becomes practically zero, as can be seen from the curve Fig. 2, and hence the capacity of the condenser becomes equal to the geometric capacity. In other words the capacity of the condenser approaches the geometric capacity as the frequency is increased.

By similar reasoning, and these involving only elementary principles, other predictions may be deduced.

A further development of this idea is under preparation.

1. Dietric in Phys. Zs. 11, p. 187, 1910 shows that $R_t = R_0\, e^{\frac{-qt}{273(273+t)}}$ q being a constant depending on the material and t the temperature.

E. R. Le Ghait: Professor Karapetoff's mathematical analysis will certainly be of great interest to all those occupied with the behavior of dielectrics. He does not make any assumption on the physical nature of the phenomena. The work we have done with fibrous insulating materials has led us to the opinion that Maxwell's ideas are, in that case, quite capable of explaining the observed phenomena, provided however, one takes into consideration the complicated structure of the dielectric. We believe that the absorption as well as the dielectric losses at commercial frequencies are due for the greater part to the presence of very small quantities of moisture imprisoned in the capillary tubes of the fibers. If we then consider the dielectric as composed of a very great number of very thin paths crossing from one electrode to the other, and apply Professor Karapetoff's analysis, his function $F(\alpha)$ will be the law of distribution of the moisture among those paths. If the curve $F(\alpha)$ has a very pronounced peak it will indicate that all the paths have pretty much the same amount of moisture. If on the contrary $F(\alpha)$ is a comparatively flat curve it will indicate that some paths contain much more moisture than others.

If then the moisture is the cause of the dielectric loss the knowledge of the function $F(\alpha)$ will give us an indication of whether the loss is uniformly distributed all over the dielectric or whether it is for the greater part concentrated in some of the paths, these paths constituting possibly weak spots on account of the deterioration of the insulation due to an exaggerated loss in a given point.

Dr. Whitehead, in his comments of Maxwell's theory, calls attention to the fact that pronounced absorption is observed in substances that can have in them only small amounts of impurities. This is probably due to the peculiar shape of the lines of force in a dielectric containing materials of different specific inductive capacities.

Our own experience agrees with Dr. Whitehead's opinion that dielectric losses are closely related to absorption. In fact, in the case of unimpregnated paper, starting from residual voltage curves obtained with a dielectric previously left charged at 100 volts d-c. for a certain time and then left short circuited for a very short time, we are able to compute 60-cycle losses with less than five per cent error.

In the case of oil-impregnated paper, greater difficulties are encountered, as in that case the law of superposition does not hold true (this being probably due to movements in the oil under the influence of the electric field, of moisture and other components of high specific inductive capacity). In correlation with this, the power factor at a given frequency varies widely with the value of the applied voltage. It may, however, prove to be possible in the future to make a low voltage d-c. absorption test enabling one to predict with sufficient accuracy the a-c. losses at a voltage many times higher, and perhaps even to predict the curve of variation of power factor with applied voltage.

Discussion at Cleveland

PAPERS ON PAPER-MACHINE DRIVE

(STAEGE[1], ROGERS[2] AND NORRIS[3])

CLEVELAND, OHIO, MARCH 18, 1926

T. D. Montgomery: Mr. Staege says that a speed adjustment of from 0.1 to one per cent is required. Does this mean that some classes of paper require 0.1 per cent while others require one per cent, or that regulation anywhere between 0.1 per cent and one per cent meets all conditions of paper making?

Reference is made to differentials, either electrical or mechanical, and Mr. Staege refers to the accumulative lag in drive and master shaft and field clutch. Would there not be the

2. A. I. E. E. JOURNAL, April, 1926, p. 323.
3. A. I. E. E. JOURNAL, May, 1926, p. 432.

equivalent lag with either the mechanical or electrical differential, in so far as affecting the regulation?

L. W. W. Morrow: The object of all of these drives as outlined in the papers seems to be to answer the speed-regulation requirements in the production of paper. I should like to see something that would show the response of these drives to the actual requirements; in other words, if there is a change in load in any one section, what is the time interval until adjustment to that situation by the drive? Each drive has been described, but we haven't definite time data as to the results accomplished by the drive.

F. C. Bowler: We have heard a great deal about the exact regulation which will be produced by these various types of drives and emphasis has been put on the need of exact regulation. I presume that the authors have made some experiments tending to show what the actual regulation has been with the various types of mechanical drive which we have had in the past. I wish that might be brought out. In other words, it is a question in my mind whether we aren't putting emphasis on something that is more refined than we need. We have made paper a good many years with belts and gears, and personally I doubt if we have ever had such regulation with mechanical drives as any of these new sectional drives will give us.

N. D. Paine: I would like to agree with Mr. Bowler and say that we are inclined, perhaps, in the sectional drive, to attain too exact speed requirements. As he said, we have made paper for years with belts and pulleys, and now, with the electrical drive, it is more a question, especially on the large 234-in. machines, of starting the dryers than of the actual speed control.

We do get exceptionally good speed control with the mechanical interlock, of which our company has four on the 234-in. machines.

The papers lay quite a bit of stress on the fact that there is a large amount of stored energy in some types of motors. With regard to the mechanical interlock drive, that stored energy is used to very good purpose. The master shaft being driven from the dryer section of 34 6-ft. dryers, weighing 12 tons each, naturally maintains an extremely steady speed, as the energy stored in this section smooths out any slight speed variation which might occur due to small voltage fluctuations.

Coming down to the various section motors, I can say, especially on the couch—which we have watched more particularly—that speed control, where the paper is the weakest, with our Harland or mechanical interlock, is maintained with a small field variation, from 0.05 to 0.10 ampere, in the shunt field, which is with the machine running at 750 to 800 ft. per minute.

H. L. Sanborn: There seems to be a question as to exactly what basic principles the electrical manufacturers are endeavoring to correct with their electric drive.

Mr. Staege refers to a steel mill as having a very heavy load, which would not exactly apply to the electric drive. There is little comparison between the steel-mill and the paper-machine variable loads, yet a plugged calender will subject its motor to two and one-half times its starting torque, probably as great a variation as the steel mill when the ratio of power in use is considered. This and other inherent conditions peculiar to paper-machine operation produce a system of variables making load changes one of the big factors the electric drive is called upon to correct.

These load variables may be caused by mechanical conditions, vacuum changes on the wire, poor bearings, sections out of alignment, stock changes, clothing, etc.

We have in the Abitibi Mill at Iroquois Falls the Westinghouse electric sectional drive. We find it more reliable than our mechanical types after four years of operation. The whole machine has greater flexibility. The operating efficiency has increased and as a whole the close regulation tends to produce greater tonnage over the corresponding machines of the same size having mechanical drive. The breaks on this particular machine have decreased and there has been a reduction in repair labor and material.

In the main, however, I think, we have perhaps forced upon the manufacturer of electrical material a very severe problem, but you must endeavor to bear this in mind:—The paper mill has been running for years and years, as Mr. Bowler states, and the electric drive is endeavoring to take up these old-time conditions and produce results superior to the mechanical type of drive, without redesigning the paper machine to fit the electric drive.

Our sectional drive has accomplished this feat at the Abitibi mill and the average operating efficiency on our paper machine equipped with this drive, conditions being equal, has not been exceeded, and on the average has not been approached by either the mechanical or non-sectional electric-driven machines in our plant.

J. F. Rhodes: I think my two friends who have just spoken have brought up very important arguments. I believe the Mead Pulp & Paper Company put in two of the first drives.

I think the main object in the machine drive is to keep the sections together, that is, synchronized. With the old machines we had an engine that required steam pressure to be constant all the time. Then we depended upon the governor to maintain the speed. After the paper maker got his paper over the machine, he had nothing more to worry about unless his thickness changed or something caused a break.

As we get into the electrical drives the main thing seems to be to get away from the engine and the only problem left is to supply the steam for drying. However, paper makers feel that if anything breaks down it will do so at the weakest point. If these things become so complicated that a brush gives away or a contact goes, we have to hunt the trouble, and in the meantime we may have lost three or four hours of production. The old type of machine was so simple that almost any paper maker could very quickly find out what the trouble was and get started quickly.

In building a new paper mill I do not think there would be any doubt that he would adopt the extraction type turbine and put in the late type of electric drive, getting the one that was the simplest, and required the least amount of space, and of course the financial end would come in.

I think we should aim towards simplicity in choosing drives. I do not believe there is any change in the load of the machine after it is started and the paper is going over the machine perfectly. If there should be a break at the calenders there probably would be a change in load there for a while which would react back to the motor-generator set and that would in turn slow down, if it was not properly regulated, reacting back into the machine again, causing another break.

R. T. Kintzing: These papers are so broad in scope that they necessarily have devoted but a limited space to electric control used on sectional drives. Control designers should be credited with solution of the very difficult electrical problem of precise motor-speed regulation. I should like to point out a few of the other control features involved in this application, and also to supplement the statements made in some of the papers concerning the various types of speed regulators.

Starting, stopping and inching are the usual operations required in controlling the individual section motors. Certain sections are occasionally reversed, others are temporarily slowed down, and other motors start and stop simultaneously. Running-load conditions are usually constant. Starting-load conditions may be those of a friction load or those of a load having high inertia. The latter are the most difficult to regulate. Starting-load conditions on the dryer and calender section are unusually severe.

Individual resistor-type automatic starters having positive time-limit acceleration are best on account of starting from a bus, the voltage of which may vary over a broad range to provide for different machine speeds. Push-button-operated starters with motor-driven cam-operated accelerating contactors have proved

very satisfactory. Time-limit overload and low-voltage protection is necessary. Starting motors at full field strength is desirable to obtain high starting torque with minimum starting currents.

The armatures of the section motors are connected to an adjustable-voltage generator while their fields and the control circuits obtain power from a constant-voltage exciter generator. All circuit breakers, disconnect switches, etc., should be connected to interlock the two sources of d-c. power and prevent damage from incorrect sequence of operation. It should be impossible to energize the control circuit of any section motor unless all of the switches furnishing power to the motor circuits are closed. Opening any switch should immediately de-energize the control circuits of all sections depending upon power supply from that switch.

Auxiliary motors driving exciters or blowers for forced motor ventilation should have their control apparatus interlocked and connected to insure their operation when the power-supplying generator is started and to cut off the power supply in case of overload on these auxiliary motors.

The many panels necessary for controlling and regulating the required apparatus should be assembled into one switchboard which can be located remote from the heat, water and dust of the machine room and under the charge of authorized workmen.

In addition to the usual push-button stations for starting, stopping and inching the section motors and for changing the speed of the entire machine, there is furnished with the equipment described in Mr. Staege's paper a "Safe-Run" station for each section which permits the section control to be made safe when it is necessary to work around dangerous parts of the machine and which cannot be restored to the running position until unlocked.

Heavy dryer sections and calenders require starting torques many times in excess of the running torque, while presses and other sections usually are started at reduced load and do not need much more than normal torque to start. If the range of operating speed and voltage is broad, special provision must be made to change the value of starting resistors as the voltage changes.

When starting currents become large enough to overload the generator, and cause undesirable voltage variations, means must be provided to obtain the necessary torque without these objectionable features. Separate low-voltage generators for starting purposes, separate starting motors, and series-parallel controls are methods in common use. In the case of dryer sections geared together, satisfactory stable division of the load on the driving motors can be obtained by a proper design of the motor. Motors having good speed regulation are necessary, but these unfortunately will not ordinarily parallel with equal division of load. It has been possible by means of special windings to design motors which have excellent speed-regulation characteristics and at the same time divide their loads equally when geared together.

A successful speed-regulating system must have ability to hold constant motor speed in spite of the various causes tending to change it, must respond quickly enough to avoid damage to the partly finished sheet of paper, and must operate with a minimum of attention. If the regulator can make a change in field strength of sufficient magnitude, can make it fast enough, and can stop when exactly the right amount of change has been made, successful operation is assured. Ruggedness and serviceability must be obtained in the design to make it a commercial success after these fundamental requirements have been secured. The most important features of the regulator described by Mr. Staege is its ability to produce a perfectly graduated change in effective value of the field resistor by the simple method of intermittently short-circuiting resistor steps by means of a conductor having a variable width. Enough resistor steps can be used to give all of the regulating capacity ever needed. Unlike former systems, the amount of resistance is not limited by the master speed. Those sections having high inertia and requiring more gradual changes in resistance can be equipped with smaller-pitch screws. As a result it is not necessary to sacrifice regulating capacity on the high-inertia sections and the lighter sections can be made to respond more quickly. An infinite number of resistance values between maximum and minimum may be secured. The regulator is truly differential in action and must produce 100 per cent speed correction before its action stops. Mechanically the apparatus employed is simple and substantial. It is evident that this system possesses to a very marked degree all three of the fundamental requirements: capacity, quick response and smooth regulation.

E. F. Bearce: The sectional electric drive for paper machines has accomplished some very definite results for the industry.

In the manufacture of news print, this drive is especially advantageous since it permits of the high paper speeds with positive regulation. For the higher-grade paper manufacturer the drive has provided regulation of speed which is one of the important features required to get a sheet of uniform weight and caliber. These points of advantage are in comparison with the older methods of drives using a variable-speed back line in which the speed may be limited by belt or pulley design and the use of a variable-speed steam-engine drive having a regulation not less than three per cent.

It is also interesting to compare the cost of the sectional drive with the variable-speed drive using a back line, both as to first cost and maintenance. It has been determined that the first cost of the sectional electric drive is a little greater than the back-line drive, but is considerably more economical as regards maintenance.

The papers have brought out some very interesting points as to the details of construction and arrangement of the three different drives, each one having distinct points of advantage, and all three in successful operation in different parts of the country.

The manufacturers of this equipment are to be congratulated on the development of this drive as one of their greatest contributions to the advancement of the paper industry, and I am sure every paper maker is ready to cooperate with them in the continuance of their good work.

E. B. Wright: We operate seven machines; three of them are driven electrically by d-c. variable-speed motors through a line shaft with cone pulleys and friction clutches.

This type of drive works out very nicely, the regulation being good if the exciter voltage remains constant. The least variation in exciter voltage causes a change in speed of the d-c. motors.

A motor-generator set, with exciter direct-connected, is used to drive the variable-speed lines. This set takes its power from an extraction turbine, which when operating at maximum rating and extracting the maximum amount of steam, at times falls below normal speed, which affects the exciter voltage causing a variation at the paper machine.

I should like to ask the speakers how the cost of installing the individual drive compares with line-shaft drive in new installations, also how maintenance costs compare.

R. S. White: Mr. Wright mentioned a variation in speed of the prime mover causing a speed change on the paper machine. My experience has been the same.

We have a synchronous motor-generator set with exciter direct-connected. This exciter supplies the excitation to the d-c. generator as well as the synchronous motor. Therefore any slight change in speed causes a voltage variation in the d-c. generator due to the exciter voltage varying.

When first starting, we had considerable trouble with the governor of our turbine and consequently had all sorts of speed variations. Now if the paper-machine head box were set

for, say, 25-lb. paper at 300 ft. per min. and then the machine suddenly changed to 325 ft., it would cause the paper to drop in weight and change the dryness at the same time.

All paper-machine drives, in my estimation, should have voltage regulators to take care of just such trouble as we experienced. I understand that all Harland drives are now furnished with voltage regulators.

The Harland drive for our No. 2 machine has been in operation four months and the No. 1 machine two months. Outside of the trouble mentioned we have not any fault to find with the performance of the drives.

When we started the No. 2 machine we had a suction press roll 22 in. in diameter. Soon this was removed and a 26-in. rubber press roll installed. Since this roll was 4 in. larger, it had to run slower. Now the field rheostat or regulator did not have a range wide enough to cover this, so we had to change the gears and get a larger ratio.

It seems to me that these regulators should be designed to cover a much larger range than they do in our machines, as paper mills change managers and each one wants different equipment. And in order to drive this equipment extra gears must be kept in stock.

Mr. Norris mentioned something that seems to me is more important than close regulation between sections, and that is the control of the supply to the machines. Why not have the pumps interlocked so as to give uniform supply? If the supply to the machine is not fed on the wire at a uniform rate, the paper cannot be of good quality. There should be an automatic arrangement so that in case the machine changed speed, the opening from the head box (if a Fourdrinier machine) would change in direct proportion to the speed.

C. A. Farrell: We have all three drives, single-motor, sectional and mechanical. I guess the proof of the pudding is in the eating, and all of our machine men are unanimous for the electric drive. We find that they like the sectional drive the best, although I can't see but that we get almost as good regulation with the single motor. Of course, we have belt trouble. I notice that one of the manufacturers has a provision also, I think, in the face of the motor for cutting in some series windings. I would like to ask whether that is necessary on all of the sections or just a few, and whether it is for starting purposes only.

Mr. Norris says that he uses compound-wound motors, and the other manufacturers use shunt motors. I wonder if there is a reason for that.

I think our sectional drive was one of the first. Our motors are larger than necessary and we don't have any trouble from temperature, but I wonder if the motor is enclosed only to keep the water out of the machine or if they depend upon the forced air to keep down the temperature and therefore use a smaller motor.

I would like to know what sizes of motors are used in the drives today compared with ours. We have 35- to 50-h. p. motors, I believe.

We are particularly interested from the maintenance standpoint in the temperature of the motors. As large as our motors are, in the heat of summer they frequently run temperatures that are pretty high.

Tom Harvey: I look at this from an owner's standpoint. I am wondering if these people who put in these very expensive electric drives are getting a return on the money invested.

We have four machines making box board. I was very much disappointed that none of the speakers said a word on box board. Our tonnage amounts to the total tonnage of all of the news paper, all of the book paper and all of the writing paper made in the United States, and I think it should be recognized.

One of the authors shows a drawing of a cylinder machine and does not say a word about it.

We have one old mill that has been running about 25 years, and because of the crowding of the mill we decided some few years ago to electrify it. We have spent considerable money in that mill and I suppose it is electrified as well as any other boxboard mill with the exception perhaps of the mill at Ritman, Ohio.

We find that we don't get the return on the mill with the large investment that we do from the mill with the smaller investment. We also get much larger tonnage from the mill that is what I call directly driven from the steam engine with the rope drive. We have very little electricity in that mill.

I can readily see that the electric drive is a great advantage to the people who are making news paper and are running their machines up to a 1000 ft. a minute, but I have yet to be shown where a manufacturer is justified in spending the amount of money that he has to spend to put in the electric driven machine. I doubt very much if the stockholders would be satisfied if they could see the results from the machines that are not electrified.

J. H. Crossley: We have only just started up our first two sectional-drive machines, which are the General Electric Company's drive.

I should like to ask Mr. Norris what he means when he says that when their interlock is out of action, the wet end of the machine does not run wild? I am curious to know what would happen to our drive if our regulator should go out of action.

A. O. Spierling: I was glad to hear Mr. Harvey refer to the financial studies which must be made when considering the addition of electric drives to paper machines.

At the present time we, at Hammermill, are using the mechanical type of drive on each of our five paper machines. About four years ago we investigated the electric drive and have been giving considerable attention to it since. We credit the electrical manufacturers with doing a splendid piece of engineering work in perfecting the electric drive. Any of the three types of electric drive described, we believe, will work very well but their installation involves considerable expense which is sometimes very hard to justify.

We have thus far been unable to find how we could produce paper any cheaper by replacing our present drive with the electric type of drive.

There is one point, however, which has been brought out here at this meeting which if shown to be true would immediately touch any paper maker's heart and that is the statement that with the electric drive a better quality of paper might be produced. If this is true, the paper maker would be immediately much in favor of this type of drive because if he can produce a better quality of paper he can get more money for it and therefore justify the expenditure.

Of course, the thermodynamics of the matter enter very much into it, and it is a heat problem from start to finish. We charge against our paper machines the heat units that are used not only for the engine drive but also for the air that must be supplied to carry away the evaporated moisture.

Everything of that nature has to be taken into consideration before a person can say whether or not he is justified in putting in such a drive. It may, however, work out better with a new installation or with larger machines than it does with an existing installation of moderate-sized machines. Our machines are comparatively small compared to 300-in. machines. We manufacture a high-grade bond paper and run at speeds anywhere from about 100 ft. a minute up to 500 ft. a minute.

W. W. Spratt: One of the items touched upon is the heat balance of the paper mill. I believe it is an important subject to which we should give serious thought.

Mr. Norris, in his paper, mentioned that the 125-ton machine requires, roughly, 39,000 lb. of steam an hr. This, he estimates, is equivalent to 1000 e. h. p.

Let us assume that for the class of mills considered, power is worth from ½ to one cent a kw-hr. Mills having adequate hydroelectric development, principally in Canada, may,

of course, get power for less than a ½ cent. Depending on the cost of competing power and cost of coal in the district analyzed, it is estimated that it may be worth from $5000 to $25,000 a year as an incentive for the mill to obtain by-product power from this quantity of steam. Taking an average condition of $15,000, the average mill would hardly, under these conditions, utilize live steam through reducing valves to do the work in the dryers, which points out the importance of consideration of some sort of non-condensing or by-product prime mover as a source of power for the paper machine.

This is the question which I know Mr. Harvey, in his discussion, was referring to, especially in relation to board mills. I have seen many cases in board mills which did not have the best type of heat balance. Unfortunately, in the case of mills that do not have the heat balance worked out well, and are electrified, the story gets around that it is uneconomical to drive the mill electrically, while, with a much better heat balance, taking full advantage of the possibilities of generating by-product power, such a situation would not be so marked and the advantages of electric drive could well gap the difference of some of the losses on the pure question of steam utilization, as referred to the engine drive which unfortunately still predominates in board mills.

I believe the greatest advantage of a sectional drive is in a new mill where advantage can be taken of the smaller space and the basement can be utilized for other purposes. I know of one mill which installed sectional drive merely on the basis of lower building cost and other items which have not been discussed. They operate a board machine from 50 to 200 ft. per minute. Fortunately, they happen to be located where they can buy power from Niagara and they have a cheap power rate which assists them. Even in their case, however, there would be some advantage in using a non-condensing unit to drive the d-c. generator.

We have heard a very interesting discussion touching on the relative merits of moderate-speed motors versus direct-connected, slower-speed motors. The discussion took us into the question of stored energy of the different motors. We are chiefly interested, however, in maintaining the speed of the motors, whether we do it by means of an interlock system, synchronous-motor tie-in system, or regulator system. In this connection, I believe we all agree that the system with the maximum stored energy is less susceptible to speed changes. The stored energy tends to maintain the speed at the proper value. Our problem is one of maintaining the desired speed and a large stored energy assists us. It is only when we are away from the desired speed that a large stored energy would be a disadvantage.

I should like to ask two questions; one is with relation to the system utilizing the dryer sections as a master. I should like to ask why that is done,rather than having a regulator which is entirely independent of any one section of the machine.

I should like to ask Mr. Rogers how long it takes the vernier brush arm of the synchronous-dynamometer regulator to travel from one extreme to the other.

N. D. Paine: May I answer one of the last questions,—as to why the dryer section is used as a master section? I mentioned before that the immense amount of inertia in the dryers naturally tends to keep them at a very steady speed. As a matter of fact, using a Bristol tachometer which is extremely sensitive, we have found that when we had that tachometer on the master shaft, it would draw a straighter line than you could with a ruler for possibly four or five hours on end. It also obviates the necessity of using section regulators. You cut down your initial cost in that way.

It has been mentioned that when the dryer section is shut down the master shaft is stopped and the section motors are running wild. This is not correct. When the dryers are shut down, the section motors automatically go to the non-interlock point of the field regulator, which is only one or two commutator or face-plate segments away from the operating position of the regulator brush arm, and this position is less than 0.25 ampere in field-strength value. I happen to know that our own paper makers hardly realize that there is any difference in speed once we have our regulators set when the dryers are shut down. In fact, once the dryers are shut down, you are not making paper; you can't handle it the full width of the sheet; you can only take your lead strip up to the third press at most, so why worry?

L. E. Markle: It is common practise in paper mills to have the machine operating for 24 hours a day, over a period of six days in the week. In view of this continuous service, the mechanical duty required of the rheostat mechanism described by Mr. Norris as a breathing process must be rather severe. We should like to ask whether special precaution is taken in the selection of materials and the construction of the face plate and brush mechanism?

Several of the paper-mill representatives as well as the authors of all of the papers have emphasized the necessity for close speed regulation at all times. Since the permissible changes in speed are so small, it is certainly true that any system which will correct to a finer degree than other systems is desirable. All systems require some speed reference as a master. This unit may be a section of the paper machine such as the dryers, or it may be a unit driven by a separate motor. Since any change in the speed of the master unit affects the speed of the entire paper machine, causing it to speed up or slow down as the master speed changes, it would seem that an installation as described by Mr. Staege, where the speed of the master set is regulated just the same as the speed of any of the main driving motors, would naturally give a closer speed regulation.

I feel this point vital because as mentioned before the limits of permissible variation are small, and any system which can regulate better than another, no matter how small the amount, is preferable.

S. A. Staege: Mr. Rogers calls attention to the controversy on the relative merits of high-speed, medium-width machines as compared with medium-speed, very wide machines, and indicates that there is now a tendency to favor the former. A more complete statement would be to say that the high-speed, medium-width machine first reached its supremacy, but is now being followed by the high-speed, very wide machine, as there does not appear to be any fundamental reason why the very wide machines should not operate at equally as high a speed as the medium-width machine. Present practise indicates wider machines than ever built before combined with a maximum contemplated speed so far unapproached in actual commercial practise by several hundred feet per minute. The real limitations of the paper machine both as to speed and to width are determined by such factors as the maximum speed at which the sheet can be formed properly and by economic factors pertaining to the machine clothing, initial cost, etc., and not at all by the drive.

All available data confirm the indication that the power required by the several sections of the paper machine varies directly as the width of the machine and directly as the speed of the machine so long as the other relevant factors remain substantially constant.

I do not agree with Mr. Rogers' statement that the synchronous-motor tie-in system is a preventive and that the regulator type of control is a corrective system, nor am I able to agree that in the regulator type of control there is no restraining power to hold the motors in place. In fact, in the case of sectional drive, the d-c. motor has available a restraining torque equivalent to far more than the full-load torque of the motor, whereas, in the case of the synchronous, tie-in system, the full-load torque of the synchronous motor is far less than the normal torque of the d-c. driving motor. It is quite true, however, as Mr. Rogers has said, that the success of the regulator type of control depends upon the amount of angular dis-

placement which causes the regulator to function and by the time element of the motor field. This means that there should be absolutely no lost motion and that resistance be cut in or out of the motor field circuit with the smallest possible change in angular displacement of the motor. It also means that the time element of the motor field circuit should be as short as possible, which is inevitably associated with relatively high-speed motors.

I should like to ask Mr. Rogers if he does not feel that a speed change of a section of the machine of 0.15 per cent which he has indicated may result from a load change, in the case of the synchronous-motor, tie-in system, is not too much for satisfactory operation, particularly at the dry end of the machine. Personally, I feel that such an amount of speed change between sections is far in excess of safe or desirable limits.

In the case of the synchronous-motor, tie-in system, I should like to ask Mr. Rogers at what speed the frame of the synchronous motor is made to rotate by the small variable-speed, d-c. motor. It would appear that if the speed at which the frame rotates is a very small percentage of the rotor speed, then the change in speed of the small, d-c. motor might have to be several hundred per cent to accomplish a change in speed of the d-c., section-driving motor of, say, 10 per cent to compensate for possible changes in diameter of the roll, change in draw, etc.

I would also like to ask whether the paragraph in his paper immediately preceding the description of the synchronous-dynamometer type applies to the paragraph immediately preceding it.

From Mr. Rogers' conclusions, it appears that the three authors are now unanimously in agreement that regulator control best meets the requirements of sectional paper-machine drive.

It is stated by Mr. Rogers that the synchronous dynamometer regulator operates on an angular displacement corresponding to approximately 0.05 per cent change in speed of the controlled motor. Obviously, if there is a change in speed, the angular displacement will continue to increase until the speed is corrected and it would be desirable to know how long this 0.05 per cent change in speed must continue to obtain a sufficient angular displacement to operate the regulator.

It would be interesting to know through how many mechanical degrees the stator of the synchronous dynamometer would have to rotate to move the commutator rheostat brushes through 450 operating points. I should also like to ask what means are employed to actuate the brush on the large-step portion of the commutator rheostat. I should like to ask Mr. Rogers of what the anti-hunting features consist in the regulator equipment described by him.

Mr. Norris in describing the interlock regulating system states that in practise the brush arm quietly breathes between two contacts. I should like to ask the order of the frequency of oscillation for the various sections of the paper machine and the actual amount of angular displacement through which the d-c., section-driving motor oscillates in response to the resistance changes.

A statement is made by Mr. Norris that should the master section shut down, whether it is the dryer section or a small master motor, all the other sections automatically still continue to run at the speed at which they were first operating. I should like to ask through what means this is accomplished.

H. W. Rogers: In connection with Mr. Staege's paper, I would like to say that the General Electric Company installed and put into successful operation in 1909 a sectional paper machine drive with a definite tie-in between the sections.

Mr. Staege describes the synchronous tie-in type of drive and states that any change in load on the part of one section will affect the speed of the entire paper machine. In this connection, I wish to state that the use of synchronous motors on each section of the paper machine is analogous to a positive mechanical tie-in between the sections, and the machine operates as though driven by a single motor. Therefore, the effect on the total load of a change in load on one section is a matter of two or three per cent and the effect on the speed of the machine as a whole for such a change in load is less than 0.1 per cent.

After describing the improvements which have been made in the synchronous tie-in type of drive, Mr. Staege states that the effect of speed variation in the small d-c. motors which rotate the synchronous-motor stator frame on the main driving motor is approximately inversely proportional to the ratio of the worm gear used in driving the stator. This statement is incorrect inasmuch as the gear ratio has nothing whatever to do with the speed regulation of the d-c. motor. A small d-c. motor drives the synchronous-motor stator at a speed which permits of proper draw adjustment, this speed being only a small percentage of the speed at which the main motor is operated. Therefore, any variation in speed of the small motor directly affects the speed of the stator, but the stator speed being a small percentage of the rotor speed, its effect on the main driving unit is inappreciable.

In my experience I have found that the control of the high-speed machine is the simplest problem with which we have to contend and that the low-speed and wide machines present the greatest difficulty.

I am interested to know just where the third type of regulator mentioned by Mr. Staege is in operation and on how many machines. I should also like to ask what provision is made to eliminate a so-called wild machine when the master set is shut down.

The European drive to which Mr. Staege refers on the ninth page consists of a-c. commutator motors and has been in successful operation at the Empire Mills, Ltd., for practically two years and is now being followed up by a second installation in another mill.

S. A. Staege: I think there is some misapprehension as to the effect of inertia in the moving system with respect to the regulation of the paper machine. As Mr. Spratt indicated, where there is considerable flywheel effect, regulation is frequently easier than where there is very little. I might say that in respect to the dryer sections where there is a very great amount of flywheel effect, the rotary-contactor regulator which has been described is able to take care of the regulation just as completely as on a press section where the inertia is almost negligible. In fact, I am unable to see that the amount of flywheel effect should seriously affect the regulation of the paper machine. The amount of stored energy in the motor is so small compared with the inertia in the dryers that I look upon it as a very small factor. It is perfectly true that if there is lost motion then a large amount of flywheel effect is undesirable; in fact, it is difficult if not impossible to regulate if you have lost motion in the regulating system. It is of course true that the high-speed motor does have more flywheel effect than a low-speed motor.

The speed of the motor field is the next controlling factor, providing the regulator works instantaneously. The rotary-contactor regulator's movement is absolutely synchronous with the change in angular displacement. The only possible chance for any delay in the corrective effect is in the time element of the motor field, and with the high-speed motor the field is very quick as compared with the field of the large slow-speed motor where there is much more iron and turns and the inductance is a great deal more. The response of the armature current will follow with practically no lag as soon as the field is changed.

I am not able to follow Mr. Rogers in his conclusions that the field is not a controlling factor in the time element of the motor.

The magnetic contactor is a very reliable piece of apparatus. When the contacts are made they rub and roll together, presenting changing surfaces, and the contacts never blister nor accumulate dirt.

Mr. Montgomery inquired as to the degree of regulation required, mentioning 0.1 per cent, and asking whether that was necessary. On the wet end of the machine, between the couch and the first press, the machine can stand considerably more than 0.1

per cent variation without breaking the sheet or causing any very serious consequences. I feel that any change in speed, however, tends to weaken the sheet although it may not be very serious. Farther on toward the dry end of the machine, a variation of 0.1 per cent would cause very serious straining of the sheet and between the dryer and the calender an elongation of the sheet of 0.1 per cent would almost certainly break the sheet. There are some grades of paper, of course, that have more elasticity than others.

The differential accumulative effect referred to which applies to both mechanical and electrical differential devices is accumulative in characteristics. If there is a change in speed, no matter how small, as long as it is allowed to continue the angular displacement keeps accumulating. And the accumulated value of departure, if it is attached to something which is supposed to regulate, will become greater and greater until the required action has taken place. The rapidity with which the corrective effect will be brought about is dependent upon the relations between the various parts, gear ratios if it is gears, or some other similar factors in determining the speed at which the secondary movement takes place.

Mr. Bowler called attention to the degree of regulation as compared with that of the mechanical drive. As brought out in these papers, mechanical drives are subject to belt slippage, and it is very well known that belts are liable to slip anywhere from a small fraction of a per cent to two or three per cent, depending upon the loading or condition of the belt, the arc of contact with the pulleys, the tension and numerous other factors. Of course, the amount of belt slippage, other things being equal, is nearly a straight-line function of the load transmitted, and if the total slippage, for instance, is two per cent under full load, a change in load of 10 per cent could be expected to produce a variation in that slippage of 0.2 per cent. However, a little moisture on the belt is likely to cause variations in the slippage of considerably larger values. It is the variation in slippage which affects the draw rather than the total or base slippage. If the drives all slipped exactly the same amount and never changed, you would have just as good a draw as though they did not slip at all.

Mr. Paine speaks of starting the dryers and comments on the stored energy. It is true, as I have indicated, that there is a great deal of stored energy in the dryers and they have to be started more slowly than the other sections of the machine. But if the proper time element is given they should be brought to full speed and synchronized with the control system without any difficulty. And where the regulator is designed in such a way that it starts up with full field on the motors and then after the motor gets up to nearly the operating speed the regulator gradually cuts in the field resistance, bringing it up to regulating values, there is no shock brought about and nothing to start oscillations. Of course, if you cut in the regulating resistance suddenly in the full amount, it is possible, if it is too much, to start oscillations of the dryers which might not easily be damped out, but when the resistance values are of the correct amount and the speed at which it is cut in properly controlled, there is no difficulty.

However, it is true that on the dryer sections with large inertia, the steepness of the regulation curve should be less than on sections with less inertia, because they cannot respond so quickly. You have there not only the lag of the motor field, but you have the inertia lag of the rotating mass, and the speed of cutting in the resistance must be adapted to the torque the motor is able to develop and to the inertia of the system.

Mr. Sanborn speaks of sudden variations and overloading conditions. The rotary-contactor regulator, which has been discussed by me, is designed to take care of any changes in load from no load to 50 or 100 per cent overload and still maintain the draw, and it does it. It has enough resistance and cuts it in at a sufficient rate to prevent more than a transient change in speed. That differs from the earlier types of regulators in which there was not a sufficient amount of regulating resistance to take care of such wide changes and in which it couldn't be cut in fast enough to overcome the initial tendency to drop off in speed faster than it could correct it.

Mr. Rodes mentioned the possibility of the brushes breaking on the regulator. If a brush should break or a wire should break in the rotary-contactor control, which is nothing more than a rheostat in which every step is divided into an infinite number of small increments of resistance, all that would happen would be that the drum would move longitudinally on the shaft a small fraction of an inch. In fact, if you were to lift out one brush while running the drum would move up about 1/16 in. and present the next step, and you could take out a number of steps of resistance or cut the wires, and it would simply move up far enough to compensate for it. You would hardly see any change in the draw at all; probably you wouldn't see any.

The simplicity of the sectional drive is not fully appreciated by most paper-mill people. Electrical apparatus has been so standardized and used so long that there is no uncertainty about its performance. It will probably stand up and give good service as long as any kind of mechanical device with similar treatment. And the records show that the maintenance is extremely low, something that cannot be met or even approached by most mechanical drives. As an illustration, one drive, of which a record was sent to me recently, has been in operation just one year, and had a total maintenance expense of $21.

Mr. Bearch questions whether there is too much refinement. I believe as long as we can get refinement without complication we ought to have it.

Mr. Harvey has raised a very interesting point in regard to cylinder machines. We have sectional drives on two-cylinder machines and they are giving a very good account of themselves. The maintenance is negligibly small and the power used is about 50 per cent less than where mechanical drive is used.

The draw can be controlled with greater precision with sectional drives than with any possible mechanical drive. And it can be held where wanted.

H. W. Rogers: In answer to Mr. Staege's reference to my statement that "the speed regulator which will best satisfy the exacting conditions of operation and appearance is the synchronous dynamometer regulator," I might say that this refers only to the regulator type of drive and its latest development. The statement has no reference to the synchronous tie-in type of drive which is being furnished and will continue to be furnished for some applications.

These two types of drive are fundamentally different; they each possess certain advantages and are both successful drives and yet they cannot be considered in the same class.

The question of torque available in the motors for maintaining constant speed under varying load conditions has been brought up. It is evident that the main driving motors have an abundance of it, whether slow-speed or moderate-speed motors are used. With the synchronous tie-in type of drive the restraining power is in the synchronous motors which have 20 per cent of the main motor capacity and have a pull-out torque of 200 per cent; consequently, they will hold the speed constant within a 40 per cent change in load either as a motor or as a generator, which is well within the load changes encountered on a paper machine. With the regulator type of drive the restraining power must come from the main driving motor and it is simply a question of whether it is instantaneously available for maintaining constant speed.

Both slow-speed direct-connected motors and moderate-speed geared motors have been successfully used on paper machines, but in my experience the purchaser has shown a marked preference for the slow-speed direct-connected motor. No difficulty has been experienced in designing either type to meet the requirements and it has been largely a matter of balancing the lower maintenance of one against the lower first cost of the other.

The moderate-speed motor will not respond more readily to changes in field strength than the slow-speed motor nor will it give a greater amount of torque for starting heavy loads. Slow-speed motors with good regulation can be made.

The slow-speed motor has a heavy armature with comparatively large WR^2, while the moderate-speed motor is of small diameter with a low WR^2, and while this might appear as an advantage to the moderate-speed motor, the truth is that we are not particularly concerned with the WR^2.

The stored energy in the armature is, however, of vital importance and is a direct indication of the ease and rapidity with which the motor will respond to the regulator and to changes in field. Since the stored energy in the armature is proportional to the square of the speed, it increases very rapidly in the higher speed motor, in spite of the smaller WR^2, and is many times larger in the moderate-speed motor than in the slow-speed motor.

As a further comparison the torque required to bring the motors to full speed in a given time may be of interest. Here again is a direct comparison of the responsiveness of the slow-speed motor and the moderate-speed motor, and while such wide changes in speed are not to be encountered, the comparison holds true for any percentage change in speed.

The moderate-speed motor has fewer armature conductors and a lower armature reaction; it also has a much lower inductance in the field than the slow-speed motor. The field, therefore, should and does respond more quickly to changes in current but that question is beside the point. What we are primarily interested in is the rapidity with which the armature responds to field changes and that is an entirely different question. The advantages are all with the slow-speed motor, and in the nature of things the field of the moderate-speed motor must of necessity respond about six times as rapidly as the slow-speed motor field to be on the same basis. This is not the case, but if it were possible the moderate-speed motor would still require many times greater change in armature current to produce the same responsiveness in speed, as the slow-speed motor.

It is well known that where rapid cycles and quick reversals are required, as in rolling mills and some machine-tool applications, the moderate-speed motor is always abandoned in favor of the slow-speed motor. The most important example of this application is the high-speed elevator which is driven by the slowest speed motor (65 rev. per min.) to secure sensitive control and quick response.

As regards regulation, it should be sufficient to state that hundreds of motors have been built at speeds from 38 to 100 rev. per min. with practically flat speed curves.

The slow-speed motor not only has as much torque as it is possible to obtain from any moderate-speed motor, but it has more active material and a much greater heat-storage capacity. It will stand greater overloads and more punishment without ill effect than the moderate-speed motor.

In first cost the advantage is with the moderate-speed motor, but in all other respects the advantages are with the slow-speed motor which may be summed up as follows:

1. The slow-speed motor has a much lower stored energy.
2. It requires less torque to produce a given change in speed.
3. The armature will respond more quickly to field changes.
4. It has a greater heat-storage capacity.
5. It will stand heavier overloads and more punishment with no ill effects.

In his remarks justifying the use of moderate-speed motors, Mr. Spratt has stated that heavy inertia or large stored energy is an advantage in maintaining speed, whereas Mr. Staege has admitted that the dryers, which have a large inertia, are more difficult to control since they do not respond quickly to changes.

The stored energy of a couch or press section may approximate 29 or 30 kilowatt-seconds, whereas the stored energy of a slow-speed motor armature is probably not more than one-quarter of it. The stored energy of the modertate-speed motor armature is probably two and one-half times that of the couch or press section and constitutes the bulk of the stored energy involved.

Mr. Paine has suggested the use of the dryers as a master. This is a practise that has been followed extensively on news machines and other machines with a narrow speed range and I can see no objection to it. It simplifies the control somewhat and does not affect the speed of the other sections when shut down as the regulators retain their operating position.

On wide-range machines, however, making book kraft or heavy papers, there is a tendency for the calenders to pull the dryers ahead and change the speed of the whole machine. Consequently a master set is a decided advantage in this case.

Several discussors have intimated that perhaps the electrical manufacturers are striving for unnecessary perfection and Mr. Montgomery has asked what regulation is actually required. In actual tests on mechanical drives I have found the regulation between sections to be as high as 1.2 per cent without affecting the operation of the machine or causing any complaint, and while I do not think that this should be taken as any criterion, it does indicate that exact speeds are not absolutely essential. Any of the sectional drives thus far developed will maintain speeds far beyond the possibilities of any mechanical drive.

All of the regulators described are synchronous in type and operate on the principle of an angular displacement between the two elements, the successful operation depending upon the magnitude of the displacement which causes the regulator to function. With the synchronous dynamometer I have described, a displacement of one-quarter of a mechanical degree or less between the stator and rotor will cause the stator to move and the movement ceases when the angular displacement disappears. Under these conditions there is no cumulative effect as is common with a mechanical drive. We have made no oscillograms of the synchronous dynamometer regulator, but from close observations I have made it seems to respond instantly to changes in load such as are normally encountered on the calender. Under normal conditions of operation the vernier brush on the upper half of the commutator rheostat will have sufficient range to meet all requirements but for extreme load changes the lower brush, which operates on coarser resistance steps, comes into play. This lower brush is carried on a yoked arm between the yokes of which the vernier brush moves and until the vernier brush has made its complete travel, the lower brush does not move.

All of the regulators described operate on the same fundamental principle of shunt-field control; they all operate on the basis of an angular displacement between the two elements and it is simply a question of which one operates on the smallest displacement, and which one is the simplest mechanically and electrically and has the lowest maintenance.

Mr. Harvey has requested information regarding the cost of sectional drives and I might answer him by stating that, where a new machine is involved, it is always possible to justify the sectional electric drive over a mechanical drive with either single motor or steam engine.

The use of auxiliary series fields on the dryer and calender motors was practised to a certain extent on some of the earlier drives, but at present we use shunt characteristics on both motors and generators with saturated fields on the dryer and calender motors for starting.

The use of enclosed motors is dependent upon the wish of the purchaser, but in no case do the enclosing features affect the temperature rating nor are such features ever used to justify smaller frames.

R. N. Norris: Mr. Montgomery asked a question on the degree of control—was 0.1 per cent sufficient? I think that a little better than that is necessary. So far as I can see from measurements taken personally, the average we have got can be taken at 0.03 per cent. That is from very careful measurements taken over a period of years.

I don't think there is anything in the accumulative effect. I agree with Mr. Rogers in that.

Mr. Bowler referred to the exactness of regulation on mechanical drives. I think Mr. Staege replied to that in what he said about belt slip. I don't think I need to say anything more about it, except to say that Mr. Bowler is quite right when he says that for years paper makers have made paper on mechanically driven machines satisfactorily. That is perfectly true, but then, of course, we reached a stage in paper machines where they became bigger and they have to be operated at much higher speeds, and the increased speed necessarily led to the development of these sectional drives which, once developed, proved to be far superior to mechanical drives in several respects.

Mr. Paine referred to the question of using the dryer section as the master section, and Mr. Staege also made a comment on this point. It is of course perfectly easy for dryer sections to be controlled. It is not at all a question of not being able to control them. It is purely a question of convenient arrangement of the plant.

It is often of considerable advantage to use the dryer sections, which are heavy and have considerable momentum, as a means of giving steady speed to the master shaft. If it is desired to control the dryer section it can be easily done. But why do it if it is not necessary? Why not simplify the equipment? That is one of the things at which we have aimed, namely, simplification in construction and installation.

If, however, it is required to control the dryer sections, as is advisable on book machines, kraft machines, tissue machines, etc., etc., then all that is necessary is to drive the master shaft with a small master motor and interlock the dryer sections to that. As a matter of fact there are in operation in Canada three interlock drives so driven and two in England, the two in England being big newsprint machines and the three in Canada being smaller book machines.

I agree with Mr. Rogers that for the high-speed news machine the drive of the master section by the dryers is all right, but for book machines, kraft machines, and tissue machines, it is questionable, and my inclination is to have the master motor for driving the master shaft, and not to drive from the dryer section.

Mr. Sanborn asked what the basic principle is that we are endeavoring to correct. We are of course endeavoring to correct the degree of variation in angular movement of paper-machine rolls, and the amount of load variation we are endeavoring to take account of is the normal load variations which occur on a paper machine.

I agree with Mr. Staege that he average conditions of load on a paper machine do not vary very considerably and are nothing like as heavy as the load variation that will occur on, say, a heavy rolling-mill plant. I have seen, however, fairly large load variations take place over a period of time. I have seen a couch motor, for instance, taking as a normal load 125 h.p., go up quite unexpectedly to 160 and 170 h.p. without any apparent reason. The reason of course was something mechanically wrong in the bearings or the Fourdrinier part of the paper machine, or possibly increased suction, but with the interlock system the design of the equipment is such that we provide sufficient control and resistance to deal with very heavy overloads and to prevent suctions dropping out of step. In fact we can comfortably handle overloads as high as 200 per cent if desired. If you put into your control the extra ability to compensate for these big changes in load then it is an additionally desirable condition to have.

One discussor referred to the question of starting motors on full field. That of course we always do; in fact the motors are started on what we call "super-field," as they have the full normal shunt excitation and they have the additional heavy series turns in operation at the same time.

Another gentleman referred to the question of maintenance costs on the regulator faceplates and brush arms. All I can say in reply is that we have over 30 machines in operation in Canada alone, and we have not yet been called upon to supply any spare contacts or brush arms for these regulators. We have supplied, I think, probably along with the installations as spares, some new faceplates, and probably clients have put them into operation, but we have not known of it, nor have we ever been called upon to replace them. In fact, the amount of wear on the faceplates is practically nil. When we first went into this question in 1912 and 1913, this question of wear troubled us also, but the large equipment we installed in 1913 is still running with the original faceplates, and this question of wear on faceplates need not be taken into account.

In relation to the question of the use of direct-coupled motors of slow speed as against higher-speed motors geared to the sections, I can say that we are perfectly content to use either, and have used both with perfectly good results. All our motors are compound-wound, and the results obtained prove that the compound motors are quite capable of giving the service, and of dealing with the heavy starting torques without the necessity of inching motors. As a matter of fact I think it is one attribute to the interlock system that it will control large slow-speed compound-wound motors very satisfactorily.

Mr. White referred to an installation that had no voltage regulator. I agree with him that one is essential, and on this particular installation, I had recommended that this voltage regulator be installed. On the whole I believe voltage regulators do improve operation, but we have had some extraordinarily good results without voltage regulators. The Laurentide machines, which have operated over 1000 ft. per min. since August 1921, have no voltage regulators and I say without exception that the machines are among the safest in existence today.

The question has been asked as to the amount of draw control that can be allowed at each section to compensate for the change in roll diameter from, say, 22 in. to 26 in. This is entirely one of previous decision in the design of the equipment; usually, we allow 20 per cent, but if somebody wants 50 per cent it can be given. If they want to make the equipment so that they can change rolls with ease, it can be given. The average paper machine does not need such a condition as this; in fact, I think it is the first time that I have ever heard of such a condition as this being required.

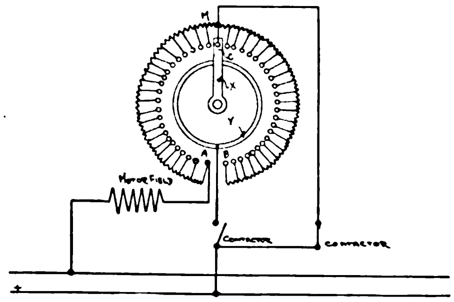

FIG. 1

Mr. Harvey referred to the question of finance and the application of the drive to the cylinder machine, and made the statement that he did not see where the increased cost of the sectional drive warranted its installation on book machines, or how its installation was warranted in taking out an old machine and replacing it with a sectional type.

I think the question of the cost of the drive is bound up with the results one can get. We have installed drives on book machines which have given so much satisfaction to clients that they say the installation is more than warranted by the results they have obtained.

Of course, where the book machines are going to be operated at higher speeds, sectional drive is the only thing. We have book machines on order today that go up to 850 ft. per min. I received an order recently for one book machine which is to have a speed variation of from 150 ft. to 850 ft. That is to be 170 in. wide, which is a pretty big book machine.

Mr. Crossly asked what I meant by saying that the machine was not "wild" when a certain master section was shut down.

This can be explained by reference to the accompanying diagram, Fig 1. *A* is the full field position; *B* is the weak field position with all resistance of the regulator in circuit. *C* is the normal working position of the arm. The arm *X* makes contact from *Y* ring to contact *C* through the carbon brush. Possibly *C* may vary one contact or two contacts, as the case may be, but it is only a very tiny bit and gives only a very tiny difference in field current.

When the master section shuts down the arm, *X* travels around, but the connection from the + busbar to *Y* is broken by an automatic contactor operated when the dryer motor is shut down, and, in place of the connection being made through the ring *Y* and arm *X* to the point *C*, connection is made through another contactor to what we call the "mid-point" *M* on the resistance itself.

As a matter of fact the two contactors are combined in one, one of which opens, and the other closes, when the dryer motors shut down.

The resistance connection *M* is adjustable in the right working position for the paper machine, and it is found that this always remains in about the same position, no matter in what position the paper machine is working, as the equipment is designed to operate at the same field current on high-speed machines all the time. Where variation of field current is required for wide-range machines the motors are designed so that, by the alteration of one combined rheostat, all field currents are operated at the same time in the same degree, and the arm remains in the same position.

I think the above remarks also apply to Mr. Staege's question as to what happens when the master shaft shuts down.

One gentleman referred to the question of thermal conditions in the mill. This opens up a very interesting phase of the whole subject of sectional electric drive, and one to which I have given a little thought, of late. It is a very interesting study, and I say that by the use of sectional electric drive it is possible to obtain a better heat balance than with any form of mechanical drive. My reasons for this statement are too long to enumerate here, but it is a subject which deserves considerable investigation.

One gentleman raises the question of carrying the paper through to the third press if the dryers are shut down. This is not an important matter in spite of what some paper makers may say, because, if you shut down the dryer sections for anything at all, it means a stoppage of several minutes. During this time, much the best place to let the paper go to is the pit at the couch, and, as a matter of fact, there has lately been installed in the mills of the International Paper Company at Three Rivers a device that, when the paper breaks at any section of the machine, will automatically break the paper at the couch. I think this is good practise.

Mr. Staege asked the order of frequency of oscillation for the various sections of the paper machine. The frequency of breathing of the regulator arm is an absolutely mechanical reflection of what is happening in the paper machine room, and it is therefore possible to count the oscillations and the time period in which they take place with the interlock equipment.

A feature which is of considerable assistance to the paper maker is an indication that the sectional drive is working satisfactorily. I would not call this oscillation; in fact there is no oscillation. The arm breathes quietly—and I emphasize "quietly"—from contact to contact, often taking a very considerable period of time to do it; in fact, I have personally sat and watched the arm work without seeing it move an amount appreciable to the eye, for over a quarter of an hour.

The average speed of movement over the working range of the arm, under normal operating conditions, varies a little, but when it is calculated into items of percentage of the variation in feet per minute of the paper, it works out, as I previously said in reply to Mr. Montgomery, to the order of 0.033 per cent.

Mr. Staege, in his description of the interlock drive, I think, has quite inadvertently used the past tense in reference to many of his verbs, when he says that the dryer shaft "was" driven, etc., etc.; and all I can say is that the present tense is more applicable, as the drives not only "were" working satisfactorily, but "are" working satisfactorily, and "will" in future work satisfactorily.

Then there is the question of this "backlash" which he visualizes, and this elastic master shaft, and with all this "backlash" and "elasticity," it is a wonder that the interlock drive has been able to do anything at all. But facts show that it *does* do it, and does it with remarkable success, and today holds unbeaten records for output in the way of tonnage on the machines, one machine having produced as much as 127 tons of newsprint in 24 hours, and having given an average, over a period of months, of 114 tons per day.

Furthermore, the average highest operating speed is held by the interlock, since August 1921, on the Laurentide machines.

Mr. Staege, in his description of the new system, uses the word, "automatic" regulation. I do not quite see how he claims that this is automatic. The regulator in itself cannot change the field, and the multiplicity of contact which he refers to is an endeavor to get slide-wire effect, but in my opinion is not necessary.

It is that which is at the back of the regulator which does the work, that is, the screw in the worm, which is in the nature of a mechanical differential, and I do not quite see how Mr. Staege can claimthat this entirely is an electrical differential.

I refer again to the question of having something in our equipment which the naked eye can see is happening, which is an instant reflection of what is happening on the paper machine roll, and that is the movement of the regulator arm. It doesn't matter whether you have 10 ohms in between stops, or 1000 ohms,—as long as the arm is only moving a short distance, it is an inner mechanical connection back to the regulator, unless the belt is slipping, and if the belt slips you couldn't make paper. There is something which is a mechanical indication to the eye independent of time lags of field, independent of back lash, independent of elastic shafts.

The question of the vernier on a rheostat is a matter of opinion, I think. Mr. Rogers described the interesting vernier they have employed on their regulator type. I think it is quite good. As a matter of fact we had also a vernier once upon a time, but we didn't carry it any further. We thought it was an additional complication, and we left it out.

Mr. Rogers referred to the question of the master shaft driving the high-speed machine. He says he has no objection to that. I quite agree with him. I think it is quite a sound scheme. If anybody insists on regulating it, it can be regulated.

On book-paper machines and kraft-paper machines I agree with Mr. Rogers that the calender can pull round the dryers through the paper alone. I have one kraft machine in mind which has a 75-h.p. motor on the calender and two 75-h.p. motors on the dryer. I have seen the calender pull 125 per cent full load, and the dryers practically no load.

We had another very interesting study once when we tried to drive a Harper machine. First, it gave us a lot of trouble simply because we did not appreciate (not being papermaking engineers) the conditions of a Harper-machine wet end. This machine has interconnecting felts between the couch and the first press, and the first press and the second press. The felts actually acted as belts and one would find that first, the press

motor was pulling the couch motor round as a generator; and then the couch motor would pull the press motors round as generators, depending upon the tension of the felts. Having discovered the difficulty, alterations were made within twenty-four hours, which enabled the machine to perform under all conditions required of it, and it is today running with absolute satisfaction.

A reference has been made by both Mr. Staege and Mr. Rogers to a new drive at the Empire Paper Mills in England, using a-c. commutating motors. This drive works, but it is very complicated and occupies a large amount of space.

Discussion at Madison

SOME INTERCONNECTED-SYSTEM OPERATING PROBLEMS[1]

(BOYCE)

MADISON, WISCONSIN, May 7, 1926

D. W. Roper: In Fig. 3 of the paper, the greatest reduction in the operating troubles is the reduction in the interruptions due to lightning. I would just like to ask Mr. Boyce how these reductions were brought about and to what extent the reductions shown were due to reduction in number of, or severity of, the lightning storms.

Carl Lee: In referring to chart No. 3 and Mr. Boyce's reference to that, there is one point that I don't believe was touched on; that is whether or not insulators are changed while the line is hot or whether the line is killed in changing insulators.

Carl Dodd: Some companies have constant average frequency control. What effect would that have on large interconnected systems? Would it be possible to have constant-frequency control, either automatic or manual, at any or all of the principal stations, and keep the system in step?

L. E. Frost (communicated after adjournment): Mr. Boyce's statements about the division of load between generating plants are applicable only to rather special conditions of generating-plant development.

Obviously, the use of hydroelectric plants for only the peak load of the day and operation of steam plants continuously at efficient loadings is a process desirable only on systems where the hydro plants are large in proportion to stream flow. It would not be economical to design hydro plants for this type of operation unless the cost of extra pondage and extra hydroelectric generating capacity compares favorably with the cost of equal steam-plant capacity, taking into account differences in operating cost.

May I call attention to the fact that in dividing load between any steam-driven units which are in operation, the loading of each machine at its own most efficient operating point does not necessarily result in the greatest possible over-all economy for the whole group.

As an example, let us suppose that we have two steam turbo generators side by side supplied from the same steam header. One has a capacity of 20,000 kw. with its best water rate at 15,000 kw.; the other is a 40,000-kw. unit with its best water rate at 30,000 kw. Suppose that for some reason the load assigned to these two machines is 45,000 kw. At first sight it may seem best to put 15,000 kw. on the smaller machine and 30,000 kw. on the larger, thus running each at its most efficient point; but as a matter of fact, if one machine has a water rate much better than the other (as is often the case) it may be more economical to carry a larger portion of the load on the more efficient machine. Even though this decreases the operating efficiency of each machine individually, it may improve the efficiency of the pair as a whole.

To secure the very best economy possible we would want to continue the increase of load on the 40,000-kw. machine (and a corresponding decrease of load on the 20,000-kw. machine) to the point where an additional kilowatt would add no less steam to one unit than it relieved from the other.

1. A. I. E. E. JOURNAL, May, 1926, p. 462.

Mr. Boyce's scheme of a load-limiting device set so as to secure the best possible efficiency from each individual steam turbine may be excellent if all units in operation are capable of about the same efficiency, but it is open to question if there are appreciable differences between the efficiencies of the various units.

F. G. Boyce: Regarding Mr. Roper's question concerning the graph on lightning, the reduction shown is not what you would probably think it is. It is not entirely an improvement in lightning protection. In 1920 our system was quite badly overloaded and during lightning storms, trouble on one transmission line would sometimes require that other lines be taken out of service due to lack of capacity. Correcting this condition represents part of the improvement shown, the balance being an improvement in lightning-arrester design.

We had quite a little trouble with electrolytic lightning arresters at that time and had to increase the insulation at the horn gaps and under the tanks. During this period I believe the lightning arresters caused about as many interruptions as they prevented. Since 1920 the arresters have been entirely rebuilt which has assisted in reducing interruptions due to lightning-arrester failures.

In the other portion of this graph classed as equipment defects, I think the greater portion of the improvement shown is due to improvement in quality and the use of a great quantity of insulation.

In answer to the question concerning the testing and changing of transmission line insulators while hot, we do not do very much of this kind of work, although we have used the buzz-stick method of testing insulators and have changed insulators while the lines are alive by the use of "hot-line tools." We now use the 60-cycle over-voltage method of testing insulators, changing the entire string of insulators when the line is dead.

In answer to the question of frequency control, we operate the system by means of Warren clocks. As seen from the map of the system, it is controlled from three points by means of system operators, one group at Saginaw at the lower end of Saginaw Bay on the east side of the state. These men are in touch with all plants in the north and from there south as far as Owosso. At Jackson there is another group of system operators who control the system south and west as far as Kalamazoo, and still another group of system operators who control the operation of the western portion of the system. The control is all centralized at Jackson, at which place the chief load despatchers are located who supervise the work of the system operators at the other locations. When the system becomes split, the system operators are in supreme control of their separate districts until the system is connected together again.

In answer to Mr. Frost, I would say that the combination of steam and hydroelectric plants in one system allows the most effective use of the kw-hr. capacity of the hydroelectric plants and that the load factor of the various units can be improved even with plants having moderate ponds; thus for a lower investment per kw. of installed capacity, a greater kw-hr. output can be obtained.

Regarding the operation of steam plants in combination with hydroelectric plants, it is possible to improve the load factor of the units in operation. An interconnected system permits the operation of units in the manner that Mr. Frost suggests, and is the way the operation of the system mentioned is usually carried out, namely, having units at their most efficient point at all times with reference to the rest of the system.

BEHAVIOR OF RADIO RECEIVING SYSTEMS TO SIGNALS AND TO INTERFERENCE[1]

(PETERS)

MADISON, WISCONSIN, MAY 7, 1926

Edward Bennett: In order to appreciate the significance of the point of view which has been developed in Professor Peters' paper, it may be helpful to review the sequence in which the knowledge of the properties of circuits has developed. Practis-

1. A. I. E. E. JOURNAL, August, 1926, p. 707.

ing engineers were first confronted with direct-current problems, and quickly obtained a very good understanding of the properties of complex networks or combinations of circuits, provided the problems related only to the steady flow of continuous currents in the networks.

Somewhat later came the realization of the possibilities of alternating current in the distribution of power. Engineers then became concerned with the performance of circuits when carrying alternating current. That situation was cleared by the adoption (largely through the writings of Steinmetz) of the method of the complex algebra for the calculation of the properties of alternating-current circuits.

In recent years, with the development of radio telegraphy and telephony, and with the development of extensive high-voltage transmission systems, engineers have become concerned, not so much with the performance of networks when carrying alternating currents in an undisturbed manner, but with the performance of these networks when they are subject to switching operations or when they are subject to disturbing electromotive forces,—the static impulses and so on.

Mr. Peters has developed and illustrated the application of the point of view that when we want to determine the effect of a transient disturbing electromotive force upon a receiving network, we may do this by replacing the transient electromotive force with the electromotive forces of suitably selected alternators which are conceived to remain in the circuit from the beginning of time to the end of time, and by calculating then the power delivery of these alternators to the receiving apparatus. The problem in the calculation of transient currents is thus reduced to the problem of calculating the steady-state values of alternating currents,—a calculation which is widely understood. It seems to me that the spread of this point of view will do for transient-current calculations what the spread of the method and notation of complex algebra did for the calculation of the steady-state values of alternating currents.

ILLUMINATION ITEMS

By Committee on Production and Application of Light

LIGHTS TOTALING TWENTY-FIVE MILLION CANDLE POWER BURN NIGHTLY ON BROADWAY SIGNS*

With 25,000,000 candle power of light flashed against the sky each night, New York's Great White Way is a challenge to the imagination and ingenuity of the advertising artist. One has but to saunter up Broadway at night time to see how well this challenge is being met with every conceivable device for attracting the attention of the vast crowds that throng the brightest spot in the world every evening. Of all these various devices, animated lights, with the extensive variety of motions they make possible, are seen to be in predominance. For the great power of moving lights lies in the fact that they help to tell a story vividly, and the advertiser who can get his story across to the public can be sure of its attention.

Like the proverbial moth, people head straight for a light, and moving light attracts more people than still illumination. The recognition of this truth, and the fact that bright lights have a stronger attraction for the eye than ordinary light, lies back of nearly all the newest developments for producing brilliant color and startling movements in electric signs. The instinct that compels us to look toward moving objects and to observe any object that is intensely bright is probably as old as the human race. Many explanations of its origin have been offered by scientists, but the important thing to recognize from the selling point of view is that such instincts are facts that must be reckoned with in the creation of all effective advertising.

The annual Electric Sign Show held by the New York Edison Company in the spring of this year afforded a splendid opportunity to compare the powers of attraction in still lights, colored and moving lights in electric signs. This show, the fourth of its kind and even more brilliant than the exhibitions of previous years, presented the latest ideas of sixty-five manufacturers from every branch of the electric sign industry. Everything new in electrical advertising, from simple glass box signs to the latest developments in flash devices and two-color animated billboards, were demonstrated.

A few days after the show was opened to the public, a revolving disk of colored light that threw off constantly changing prismatic colors was placed under the ordinary poster in the showroom window announcing the exhibition. Immediately the number of passersby who stopped before the window was more than trebled. There was hardly a person who was not drawn to the window almost automatically by the revolving disk of colored lights. As a consequence, the attendance at the Electric Sign Show grew from the normal number expected to a record attendance. It was the brilliant changing colors that caught the eyes of the passersby, even without their being aware of the fact, and fastened their attendance on the poster announcing the Electric Sign Show.

Observation of the crowds attending the exhibition revealed that of two similar signs, one illuminated and the other plain, the lighted bulletin attracted more than twice as many spectators as the unlighted one. The still sign, however, though illuminated, did not have as strong an attraction on the crowds as the sign across the aisle in which the effect of motion was produced by using a flasher. There was something in the power of the moving lights that almost automatically caught the eye of the spectators and thus drew their full attention to the advertisements.

Approximately 5000 electric signs were added to New York's skyline during the last year, an average of about fourteen a day. The blaze of animated light that illuminates the Great White Way today is quite a different story from the first electric sign of 30 years ago, which startled New Yorkers by its daring innovation and immediately made its mark as an effective form of advertising. The first electric sign, with its two hundred lamps, would almost be lost on Broadway now.

Pacific Coast Convention

SEPTEMBER 6-9

Preparations are complete for an excellent convention at Salt Lake City, September sixth to ninth inclusive. A most interesting collection of papers dealing with a wide range of subjects will be presented and a most enjoyable program of trips and entertainment has been arranged. The program is as follows:

MONDAY, SEPTEMBER 6

9 A. M.

Registration at Convention Headquarters, Lobby Hotel Utah.

10 A. M.

Session of Counselors of Student Branches.

Meeting of Section Officers of Eighth and Ninth Geographical Districts.

12 M.

Organ Recital at Tabernacle.

2. P. M. OPENING SESSION

Address of Welcome, by Governor Geo. H. Dern.

Response by President Cummings C. Chesney.

The Space Charge that Surrounds a Conductor in Corona, by H. J. Ryan and J. S. Carroll, Stanford University.

110-Kv. Transmission Line Construction of the Washington Water Power Co., by L. R. Gamble, Washington Water Power Co.

A New 220-Kv. Transmission Line, by C. B. Carlson and H. Michener, Southern California Edison Co.

Effect of Unbalanced Tension in a Long-Span Transmission Line, by E. S. Healy and A. J. Wright, Electric Bond and Share Co.

2 P.M.

Ladies drive about city and nearby canyons.

4:30 P.M.

Excursion to Saltair; bathing, dinner and dancing.

TUESDAY, SEPTEMBER 7

10 A. M. TECHNICAL SESSION

The Circle Diagram of a Transmission Network, by F. E. Terman, Stanford University.

Calibration of Lichtenberg Figures, by K. B. McEachron, General Electric Company.

Stability Characteristics of Alternators, by O. E. Shirley, General Electric Company.

Synchronizing Power in Synchronous Machines, by H. V. Putman, Westinghouse Electric & Manufacturing Company.

11 A.M.

Ladies drive to Country Club for Luncheon, followed by Golf on picturesque links of the Country Club.

2 P.M. TECHNICAL SESSION

Vacuum-Switching Experiments at California Institute of Technology, by R. W. Sorensen and H. E. Mendenhall, California Institute of Technology.

Economical Power Factor Correction, by S. H. Litchfield.

Electrical Practise in Lead-Silver Mines in Utah, by Leonard Wilson, Consulting Engineer.

Engineering Education: Its History and Prospects, by H. H. Henline, Stanford University.

8 P.M.

Informal Reception, Ballroom Hotel Utah. Music and Dancing.

CONVENTION HEADQUARTERS, SALT LAKE CITY

WEDNESDAY, SEPTEMBER 8

10 A.M. TECHNICAL SESSION

Protection of Oil Tanks Against Lightning,, by F. W. Peek, Jr., General Electric Co.

Fire Protection of A-C. Generators, by J. A. Johnson, Niagara Falls Power Co., and E. J. Burnham, General Electric Co.

Variable-Voltage Equipment for Electric Power Shovels, by R. W. McNeill, Westinghouse Electric & Manufacturing Co.

Temperature of a Contact and Related Current-Interruption Problems, by Joseph Slepian, Westinghouse Electric & Manufacturing Co.

11 A.M.

Ladies Excursion to Pinecrest Inn, at the head of Emigration Canyon, for lunch.

2 P.M.

Golf Tournament on Links of Country Club.

6:30 P.M.

Dinner, Hotel Utah Ballroom, followed by:
Presentation of Edison Medal
Response by Dr. Ryan

THURSDAY, SEPTEMBER 9

10 A.M. TECHNICAL SESSION

Transcontinental Telephony, by B. B. Jacobs and H. H. Nance, American Telephone and Telegraph Co.

LIBERTY PARK LAKE, SALT LAKE CITY

Controlling Insulation Difficulties in the Vicinity of Great Salt Lake, by B. F. Howard, Mountain States Telephone & Telegraph Co.

Carrier-Current Communication on Submarine Cables, by H. W. Hitchcock, Pacific Telephone and Telegraph Co.

BINGHAM CANYON EXCURSION

On Thursday, September 9, starting at 12 o'clock, there will be an excursion to Bingham Canyon and Magna, visiting the famous Mine and Mills of Utah Copper Company. Basket lunch will be served. This is a novel and instructive trip and will be enjoyed by the ladies. The excursion will be timed so that afternoon blasting can be witnessed from the opposite side of the canyon.

FRIDAY, SEPTEMBER 10

8 A.M.

Excursion via automobile to Utah Power & Light Company's new 30,000-kw. hydro generating station at Cutler on lower Bear River. The trip will be over paved roads the greater part of the way, passing through the cities of Ogden and Brigham. Excursion will return to Salt Lake City in time to catch evening trains the same day.

8 A.M.

Excursion over celebrated Bear Lake-Bear River Development of the Utah Power & Light Company by automobile. This is a 400-mile trip and will require two days' time. Excursion will return to Salt Lake City Saturday evening. Comfortable hotel arrangements have been made for the night stop. Part of the trip is through wonderful mountain and canyon scenery and will be enjoyed as much for the scenic beauty as for the technical and educational benefits.

New York to Have Regional Meeting in November

A two-day Regional Meeting is planned to be held in New York City, November 11 and 12. There will be four principal technical subjects discussed; namely, secondary distribution networks, illumination, communication, and railroad electrification. A number of excellent papers on these topics has been promised. In addition to the papers, other interesting features will be arranged, including inspection trips, entertainment, etc.

The committee in charge of the meeting is as follows: Messrs. H. A. Kidder, Chairman; H. V. Bozell, Secretary; O. B. Blackwell, W. A. Del Mar, G. L. Knight, E. B. Meyer and G. H. Stickney.

Chemists in Convention September 6th

Foreign delegates to the coming convention of the American Chemical Society are beginning to arrive in New York preparatory to meeting with probably the largest contingent that has ever visited America in attendance at the convention to be held in Philadelphia, September 6th. Among these early arrivals are Sir James Colquhoun Irvine, principal of the Scottish University of St. Andrews and head of its department of chemistry, Fellow of the Royal Society, Davy Medalist in 1925, and an eminent investigator of carbonhydrates; Leonor Michaelis,* Professor of biological chemistry, University of Berlin; Professor Ernst Cohen, Physical Chemistry Dept., University of Utrecht; Dr. Camille Matignon, editor-in-chief of Chimie et Industrie and head of research laboratory in College de France; and Gabriel Bertrand, Professor of biological Chemistry at the Sorbonne, chief of the service of biological chemistry of the Pasteur Institute and internationally known as a devotee of research.

Denmark will send J. N. Bronsted, Professor of Physical Chemistry at the Royal Polytechnic Institute, Copenhagen. He is also author of several textbooks on inorganic and physical chemistry and famous in research work.

Switzerland will send Peter Debye, Professor of Theoretical Physics at Technische Hochschule, Zurich. Prof. Debye is the author of numerous researches in physical chemistry, and is the leading exponent of the theory of the electrical structure of matter as applied to the problems of specific heats, dielectrics, and X-ray analysis.

Heading the delegation from Italy will be Prince P. Ginori Conti, who will address the American Chemical Society at Philadelphia, Monday evening, September 6, on "The Development of Chemical Industry in Italy."

Nearly four thousand scientists are expected to attend the Philadelphia sessions, and hundreds of papers and addresses will be delivered.

Annual Convention of Civil Engineers in October

The fifty-sixth annual convention of the American Society of Civil Engineers will be held October 4-9, 1926, at Philadelphia, Pa. The fact that at this same time, the Sesquicentennial Exposition celebrating the 150th anniversary of the signing of the Declaration of Independence, will be in progress also at Philadelphia, will enhance the attractions of the Convention and permit of a program planned for participation in the spirit of the Exposition as well as in the pleasures and scientific progress of the Convention itself. A large attendance is expected.

*Biochemistry in the Aichi Medical University, Nagoya, Japan, and author of numerous research papers.

A. I. E. E. Directors' Meeting

The first meeting of the Board of Directors of the American Institute of Electrical Engineers of the administrative year beginning August 1, 1926, was held at Institute headquarters, New York, on Tuesday, August 10.

There were present: President C. C. Chesney, Pittsfield, Mass.; Vice-Presidents A. G. Pierce, Cleveland; W. P. Dobson, Toronto; H. M. Hobart, Schenectady; B. G. Jamieson, Chicago; Managers W. K. Vanderpoel, H. P. Charlesworth, H. A. Kidder, New York; M. M. Fowler, Chicago; E. C. Stone, F. J. Chesterman, Pittsburgh; H. C. Don Carlos, Toronto; National Treasurer G. A. Hamilton, Elizabeth, N. J.; National Secretary F. L. Hutchinson, New York. Present by invitation: Past-President William McClellan and Dr. C. H. Sharp, President, U. S. National Committee of the International Electrotechnical Commission.

The minutes of the Directors' meeting of June 23, 1926, were approved as previously circulated.

A report was presented of a meeting of the Board of Examiners held July 26, 1926, and the actions taken at that meeting were approved. Upon the recommendation of the Board of Examiners the following actions were taken upon pending applications: 10 Students were ordered enrolled; 117 applicants were elected to the grade of Associate; 6 applicants were elected to the grade of Member; 2 applicants were transferred to the grade of Member; 1 applicant was transferred to the grade of Fellow.

Upon the recommendation of the Committee on Student Branches, authority was given for the organization of Student Branches of the Institute at Louisiana State University, Baton Rouge, La.; University of New Hampshire, Durham, N. H.; and Princeton University, Princeton, N. J.

Sections 46, 62, and 73 of the Institute by-laws were amended to read as follows:

"SEC. 46. The expenditures for transportation of Section delegates as referred to in the constitution shall be paid from the Institute treasury at the rate of ten cents (10c) per mile one way from the place of residence to the meeting place."

(This was done in order to place upon the uniform basis of ten cents per mile one way, the payment of traveling expenses of all delegates, officers, etc.)

"SEC. 62. The Board of Examiners shall consist of twelve Fellows of the Institute. The duties of this Board are defined in Section 44 of the constitution."

(To provide an increase in the number of members.)

"SEC. 73. The Committee on Award of Institute Prizes shall consist of the Chairman of the Meetings and Papers Committee acting as Chairman, and the chairmen of the Publication Committee, the Research Committee, and the chairmen of such other committees as the Board of Directors may designate."

(A change in personnel by the substitution of the chairman of the Research Committee for the chairman of the Committee on Power Transmission and Distribution.)

The Board approved plans for Regional Meetings, as follows: North Eastern District (No. 1), May 25-27, 1927, at a place to be decided by the District officers; Middle Eastern District (No. 2), April 14-16, 1927, at a place to be decided by the District officers; South West District (No. 7), February 14-15, 1927, Kansas City, Mo.

The appointment of committees, and of representatives of the Institute on various bodies, for the adminstrative year beginning August 1, 1926, was announced by President Chesney. (A list of these committees and representatives appears elsewhere in this issue.)

As required by the by-laws of the Edison Medal Committee, the Board confirmed the appointments by the President to the Edison Medal Committee, for the term of five years ending July 31, 1931, as follows: Messrs. John W. Howell, L. F. Morehouse, and David B. Rushmore; and the Board elected the following from its own membership to serve on this committee for the term of two years ending July 31, 1928: Messrs. B. G. Jamieson, H. A. Kidder, and G. L. Knight.

The following Local Honorary Secretaries were reappointed for the term of two years ending July 31, 1928: W. Eldson-Dew, for Transvaal; A. S. Garfield, for France; Carroll M. Mauseau, for Brazil; and F. W. Willis, for India.

A report was presented from a special committee appointed last year to consider the technical activites of the Institute, and upon the recommendation of that committee the Board adopted the following resolution:

"RESOLVED: That, effective with adoption of this resolution, the several Technical Committees shall assume a joint responsibility with the Standards Committee for the development and maintenance of such Institute Standards as come within their respective activities. Each technical committee shall report to the Committee on Standards such new standards or such changes in existing standards as are deemed desirable. Such recommendations shall be complete as to wording of any proposed standards. The Committee on Standards shall investigate and act on every such recommendation."

The Board approved a revision submitted by the Standards Committee, of Standards for Resistance Welding Apparatus (Section 39).

In acceptance of an invitation from the Committee of Award of the Kelvin Medal to nominate a candidate for consideration in the award of the 1926 Kelvin Medal, the Board voted that Sir Oliver Lodge be designated as the Institute's nominee.

The Secretary reported that the late Carl Hering had bequeathed to the A. I. E. E. and the Franklin Institute his books and professional apparatus, and that the matter had been referred to Director H. W. Craver of the Engineering Societies Library, who had arranged with the Franklin Institute for a division of this material.

Other matters of importance were discussed, reference to which may be found in this and future issues of the JOURNAL.

New Reports on A. I. E. E. Standards now Available

Three reports on proposed A. I. E. E. Standards are now available for purposes of criticism and suggestion before final adoption by the Institute. Copies may be obtained without charge by addressing H. E. Farrer, Secretary, A. I. E. E. Standards Committee, 33 West 39th Street, New York, N. Y. The reports referred to are as follows:

"Report on Lightning Arresters and Other Apparatus for Protection Against Abnormal Transient Voltages." This report was developed by a Working Committee of the Standards Committee under the chairmanship of F. L. Hunt, Chief Engineer, Turners Falls Power & Electric Company. This report covers service conditions, definitions, classification, rating, performance, earths and their resistances and dielectric tests for the following types of apparatus: Lightning arresters and diverters, lightning choke coils, high frequency absorbers, overhead grounded wires, earthing contacts and their resistances, length of connection between arresters and their earthing contacts or grounds.

"Report on Hard Drawn Aluminum Conductors." This report was developed by a Sectional Committee of the American Engineering Standards Committee under the sponsorship of the A. I. E. E. Mr. C. R. Harte, Construction Engineer, Connecticut Company, served as chairman.

"Report on Standards for Electrical Measuring Instruments." This report was prepared by a Working Committee of the Standards Committee under the chairmanship of G. A. Sawin, Westinghouse Electric & Manufacturing Company. The scope of the report is given as follows: Standards applying to the following kinds of indicating electrical instruments for direct current and alternating current; ammeters, voltmeters, wattmeters, reactive volt-ampere meters, frequency meters, power factor, reactive-factor and phase-angle meters, synchronoscopes.

Two New Swiss Standards Available

Standards for transformers not exceeding 500 volt-amperes and intended for interior installations. Special rules applying to transformers used in connection with bells, lock controls, and portable lamps, have been developed because of the conditions under which such apparatus is installed, often in damp inaccessible places and without intermediate circuit breakers.

Standards for insulated conductors for interior installations. The revision of the rules for erection and maintenance of interior installations has necessitated the working out of new standards for insulated conductors. To identify conductors that satisfy the new rules, a thread characterizing this quality has been introduced. Test methods are described in detail.

Both above standards may be obtained at office of General Secretary, Association Suisse des Electriciens, 301 Seefeldstrasse, Zurich, Switzerland.

American Engineering Standards Committee

A. E. S. YEAR BOOK FOR 1926

The 1926 edition of the American Engineering Standards Committee's Year Book is now ready for distribution and may be obtained by application to the secretary, P. G. Agnew, 29 West 39th Street, New York, N. Y. The Committee reports that the movement toward standardization of industrial products has shown marked progress during the past year, with over 200 definite standardization projects in process or completed, and with 365 national technical societies, government bureaus and trade associations collaborating through approximately 1600 representatives.

El Arte de los Metales

The Engineering Societies Library has to thank Mr. E. L. De Golyer, Vice-President of the Americau Institute of Mining and Metallurgical Engineers, for an unusually interesting addition to its collection of early engineering books. Mr. De Golyer's gift is a copy of the rare first edition of Albaro Alonzo Barba's "El Arto de los Metales," published at Madrid in 1640, the earliest work published on American metallurgy.

Barba was an Andalusian, born probably on November 5, 1561. He became a priest and prior to 1590 was sent to America. In 1615 we find him in Upper Peru (Bolivia), where he served various parishes for twenty-five years or more. He also became interested in mining, and in his book speaks of locating a vein of silver and erecting a mill. He claims to have discovered, in 1690, the method of pan amalgamation, and applied it successfully on a large scale.

His book is chiefly a detailed description of the metallurgical methods used in Peru, a topic on which his years of active work made him an authority. For many years it was in great demand, and French, German and Italian translations were published. In 1670 the Earl of Sandwich, then Ambassador Extraordinary of Great Britain, to Spain, published an English translation of the first two volumes of Barba's work, but his lack of technical knowledge made this of little value, and no adequate English translation appeared until 1923, when Messrs. Ross E. Douglass and E. P. Mathewson's translation was published in New York.

Copies of the first edition of the work are extremely scarce. Douglass and Mathewson state that they could locate but three copies, all of which were in the British Museum. Mr. De Golyer's copy is the fourth known here.

Among the various editions of Barba's book, another of special interest to Americans is one in German. This was published in 1763, at Ephrata, Pennsylvania. That the publication of a German translation, in Pennsylvania, over a century after the book was written, should appear a profitable publishing risk, is an evidence of the great esteem in which the work was held. The Engineering Societies Library is so fortunate as to possess a copy of this edition, in the original binding.

HARRISON W. CRAVER

Further Diesel Machinery Developments Sought

Plans to expedite experiments in dieselizing Shipping Board vessels were authorized by the Board on July 27th, according to official announcement made by T. V. O'Connor, Chairman, on the day following. Early arrangements will be made to work with William Francis Gibbs,—a nationally known marine engineer,—and others, for the purpose of making tests on vessels coming under control of the Board.

Coincident with this announcement, the American Marine Standards Committee held a meeting in New York City to discuss the care of diesel machinery. It is understood that the committee is working in cooperation with the Shipping Board, the Division of Simplified Practise of the Department of Commerce, and other interested government organizations.

Action Expected on Radio Measures

The radio bills known as the White Bill in the House and the Dill Bill in the Senate, both of which failed of enactment in the last session of Congress, are being sent to the members of the Conference Committee from both the House and Senate, and a meeting has been called for November in an effort to iron out the differences between these bills and to prepare a measure on which it is hoped both houses can agree early in the next session. In the meantime the Department of Commerce is continuing limited control of radio through the Bureau of Navigation. Technical problems concerning the development of the radio art from a scientific standpoint are centered in the radio laboratory of the Bureau of Standards.

Control of broadcasting through the licensing system has been relinquished but it is contemplated that the Department or the new commission will be able to bring these matters under control soon after the Law is enacted.

Civil Aviation Plans

Under the new civil aviation law, the Department of Commerce has taken jurisdiction over the lighting of postal airways, markings, and emergency landing facilities, and will take exclusive control of mapping of airways, charge of radio directional work, safety inspection of airplanes, licensing of pilots, and promote civil aviation generally.

This work will be under the immediate charge of William P. MacCracken, recently appointed Assistant Secretary of Commerce in Charge of Aviation under Secretary Hoover.

Divisions will be established in the Bureau of Lighthouses, Coast and Geodetic Survey and the Bureau of Standards to take up the highly specialized air development program. Under this arrangement, according to recent statements made by Secretary Hoover and Assistant Secretary MacCracken, early stimulation of civil aviation in the United States is confidently expected.

Study of Uses of Wood in Electrical Goods

A survey to determine the suitability of various grades of lumber for uses in the manufacture of electrical goods is to be made by L. N. Ericksen of the staff of the Forest Service's Forest Products Laboratory, as announced at the Department of Agriculture.

Deposits of Manganese Found

According to a statement just issued by the Geological Survey of the Department of the Interior, discovery of manganese ore deposits in the Olympic Mountain territory, State of Washington, lends color to the belief that other workable bodies of the ore will be found in that belt.

Manganese is used in the form of alloys in the production of steel and as a dioxide for the manufacture of dry-battery cells. The statement says that from preliminary figures it appears that in 1925 the new mines in Washington supplied approximately 11 per cent of the total high-grade metallurgical ore from domestic sources.

Developed Water Power in the United States

The Department of the Interior, through the Geological Survey, has just issued a report of the amount of developed water power in the United States as of January 1, 1926. This report shows that the capacity of water-wheels in plants of 100 h. p. or more on the first of this year was 11,176,596 h. p., an increase of 1,138,941 h. p., or about 11.5 per cent since March, 1925.

The total capacity in horse power of water-wheels in water-power plants in the United States for different years follows: 1908, 5,339,391 h. p.; 1921, 7,926,958 h. p.; 1924, 9.086,958 h. p.; 1925, 10,037,655 h. p.; 1926, 11,176,596 h. p. In the 17 years since 1908 the capacity of water-wheels in water-power plants has been more than doubled.

Engineering Societies Library

The library is a cooperative activity of the American Institute of Electrical Engineers, the American Society of Civil Engineers, the American Institute of Mining and Metallurgical Engineers and the American Society of Mechanical Engineers. It is administered for these Founder Societies by the United Engineering Society, as a public reference library of engineering and the allied sciences. It contains 150,000 volumes and pamphlets and receives currently most of the important periodicals in its field. It is housed in the Engineering Societies Building, 29 West Thirty-ninth St., New York.

In order to place the resources of the Library at the disposal of those unable to visit it in person, the Library is prepared to furnish lists of references to engineering subjects, copies or translations of articles, and similar assistance. Charges sufficient to cover the cost of this work are made.

The Library maintains a collection of modern technical books which may be rented by members residing in North America. A rental of five cents a day, plus transportation, is charged.

The Director of the Library will gladly give information concerning charges for the various kinds of service to those interested. In asking for information, letters should be made as definite as possible, so that the investigator may understand clearly what is desired.

The library is open from 9 a. m. to 10 p. m. on all week days except holidays throughout the year except during July and August when the hours are 9 a. m. to 5 p. m.

BOOK NOTICES (JULY 1-31, 1926)

Unless otherwise specified, books in this list have been presented by the publishers. The Society does not assume responsibility for any statement made; these are taken from the preface or the text of the book.

All books listed may be consulted in the Engineering Societies Library.

BELT CONVEYORS AND BELT ELEVATORS.

By Frederic V. Hetzel. 2nd edit., revised. N. Y., John Wiley & Sons, 1926. 333 pp., tables, diagrs., charts, 9 x 5 in., cloth. $5.00.

The work of an engineer with thirty years of experience in the design and operation of elevators and conveyors, this book is intended as a practical guide to the selection and operation of suitable belt elevating and conveying machinery.

This edition has been revised to include the improvements of recent years, particularly in the design of idlers and elevator buckets.

THE BONBRIGHT SURVEY OF ELECTRIC POWER AND LIGHT COMPANIES OF THE UNITED STATES: arranged according to Geographic Divisions. 3rd edit., revised to May 1, 1926. N. Y., McGraw-Hill Pub. Co., 173 pp., tables, maps, 11 x 8 in., paper. $5.00.

A series of maps and tables which show the electric companies that serve the incorporated places having 2500 or more people, together with the unincorporated towns of that size in Massachusetts, Rhode Island and New Hampshire. The statistics for each state include the population, number of families, number of telephones, number of automobiles, number of domestic lighting customers, value of crops, number of factories and wage earners, value of products, the primary horse power, and the population of each urban center. Those for the companies include their capital stock, funded debt, gross and net earnings, interest, and the communities that they serve.

BRASS INDUSTRY IN THE UNITED STATES.

By William G. Lathrop. Mt. Carmel, Conn., The Author. 1926. 174 pp., port., 7 x 5 in., cloth. Price not quoted.

An interesting account of the beginning of this important industry and of its later development. The author traces the early industrial development of Connecticut, shows why brass manufacture became of interest in that locality, and traces the gradual development of the industry and of the important firms engaged in it.

COLLOID CHEMISTRY: Theoretical and Applied. Vol. 1. Theory and Methods.

By Jerome Alexander, editor, N. Y., Chemical Catalog Company, 1926. 974 pp., illus., diagrs., 9 x 6 in., cloth. $14.50.

In 1922, the editor of this work solicited the assistance of other investigators of the chemistry of colloid in the preparation of a comprehensive book on that subject. The first fruits of this collaboration are the present book, on theory and methods, which is to be followed by others on the biological, medical and technological applications of colloid chemistry.

Volume One contains sixty papers discussing a wide variety of subjects and representing many views on theoretical questions. No attempt has been made to select contributors whose ideas and opinions agree; but to give instead the views of those who are actively engaged in this work, and to leave to the reader the task of judging.

THE ENGINEER AND THE PREVENTION OF MALARIA.

By Henry Home. Lond., Chapman & Hall, 1926. 176 pp., illus., diagrs., 8 x 5 in., cloth. 13s 6d.

The author of this book, an engineer with experience of the problem in a number of tropical countries, has endeavored to summarize the results of modern research and its practical application to mosquito destruction for the benefit of other engineers.

The first section discusses the identification of the malaria carrier and the initiation of anti-malarial schemes. Drainage and malarial conditions in lowland country, in towns and in hill country is then taken up, followed by chapters on the details of preventive works, on the value of antimalarial works and on biological means of attack. Appendixes by other authors treat of mosquito netting, applied entomology and house flies.

GEOMETRY OF ENGINEERING DRAWING: Descriptive Geometry by the Direct Method.

By George J. Hood. N. Y., McGraw-Hill Book. Co., 1926. 290 pp., diagrs., 9 x 5 in., cloth. $2.50.

Presents a new method of teaching descriptive geometry, used by the author for the last six years. This method avoids the use of planes of projection, quadrants, etc., and directs attention to the object itself, in agreement with engineering practise.

HYDRAULICS.

By Joseph N. Le Conte. N. Y., McGraw-Hill Book Co., 1926. 348 pp., diagrs., tables, 9 x 6 in., cloth. $3.00.

A textbook on the theoretical principles of hydraulics, which directs the attention of the student to first principles for the solution of most problems, instead of to empirical rules or tables. The aim is to teach the student to reason out the basic equations

and to master the fundamentals of the subject first by the use of pure mathematics and mechanics.

LIGHTHOUSE SERVICE.

By George Weiss. Balt., Johns Hopkins Press, 1926. (Institute for Government Research. Service monograph no. 40). 158 pp., 9 x 6 in., cloth. $1.00.

A study of the organization, functions, equipment and cost of the Lighthouse Service, with a compilation of the laws governing it and a bibliography of sources of information about it. The book is descriptive, not critical; its purpose being to give officials, members of Congress and the public, an accurate account of the service in detail.

MATERIALS OF CONSTRUCTION: their Manufacture and Properties.

By Adelbert P. Mills. 3rd edit., edited by Harrison W. Hayward. N. Y., John Wiley & Sons, 1926. 419 pp., diagrs., charts, 9 x 5 in., cloth. $4.00.

A general text-book, somewhat elementary in character, on the manufacture, properties and uses of the more common materials. The endeavor has been to give a modern treatment in a form concise enough for class use by students of civil engineering. In this edition the text on the constitution of metals, alloy steels and alloys has been expanded, and the chapters on cement, concrete and timber have been revised.

METALLOGRAPHY AND HEAT TREATMENT OF IRON AND STEEL.

By Albert Sauveur. 3rd edition. N. Y., McGraw-Hill Book Co., 1926. 535 pp., illus., diagrs., table, 11 x 8 in., cloth. $8.00.

As might be expected after an interval of ten years, the third edition of this well-known textbook shows many changes from the second. About fifty pages of text have been added and the text has been rearranged. Much of the work has been rewritten, with the aim to make the book a satisfactory record of present views and of current practise.

ORGANIC SYNTHESES:

Edited by Henry Gilman and others. Vol. VI. N. Y., John Wiley & Sons, 1926. 120 pp., diagrs., 9 x 5 in., cloth. $1.50.

A collection of methods for the preparation of twenty-nine organic chemicals that are sometimes required by chemists and are not available commercially. These methods have been devised by various chemists and checked by others, to insure their practicability.

PRACTICAL COAL PRODUCTION: Mine Transportation and Market Preparation.

Compiled by Frank H. Kneeland. N. Y., McGraw-Hill Book Co., 1926. 354 pp., diagrs., 8 x 5 in., cloth. $3.00.

Covers the transfer of coal from the working face to the surface and its preparation for market. The compiler has selected the most approved methods from the literature on these topics and arranged the results of his investigations in a connected account.

LES PROGRES DE LA FONDERIE MOULAGE ET FUSION.

By C. Derulle. Paris, Masson & cie.; Gauthier Villars & cie, 1926. 256 pp., illus., diagrs., 8 x 5 in., paper. $0.88.

Not a treatise on foundry practise, but a review on broad lines of modern advances in founding and of the present state of the art. The author describes the methods of molding now in use, the furnaces, methods of casting and of finishing the castings. A chapter is devoted to foundry organization and cost-finding.

REFINING METALS ELECTRICALLY.

By Larry J. Barton. Cleveland, Penton Publ. Co., 1926. 414 pp., illus., tables, 9 x 6 in., cloth. $6.00.

A treatise on electric furnace practise in the foundry. The author discusses theoretical matters concisely, but devotes most attention to practical questions, such as the cost of electric melting, the choice of a furnace, preparing linings and making the various kinds of steel and iron. A selected bibliography is included.

WATER RATES AND STEAM CONSUMPTION OF MARINE MACHINERY.

By H. E. Brelsford and E. A. Stevens. N. Y., Simmons-Boardman Publ. Co., 1926. 169 pp., graphs, 8 x 5 in., cloth. $2.00.

The authors are respectively the Chief and the Senior Engineer of the Technical Section of the Emergency Fleet Corporation. While compiling standard performance curves for the ships of the Corporation they encountered great difficulty in establishing the fuel rates, which depend largely upon the water rates. A result of their experience is the present book, which presents a method for obtaining water rates and steam consumption with a reasonable degree of accuracy. The book discusses reciprocating engines, geared turbines and the auxiliary machines usual on ships. The necessary graphs and formulas are given and their use illustrated.

DIE WERKSTOFFE DES MASCHINENBAUES.

By A. Thum. Ber. & Lpz., Walter de Gruyter & Co., 1926. 2 v., illus., diagrs., 6 x 4 in., cloth. 1,50 r. m. each.

A textbook on the strength and properties of structural materials, written from the viewpoint of their use in mechanical engineering. The first volume discusses the qualities particularly needed in materials for machinery and the extent to which metals exhibit them. It also describes the methods of testing these qualities, and the varieties of iron and steel.

In Volume Two, the varieties of cast iron, structural steel, cast steel and non-ferrous alloys are described specifically, and the purposes for which each is suitable are mentioned. A chapter is devoted to such minor machine materials as wood, insulating materials, solders, etc.

PERSONAL MENTION

C. E. BURGOON has been appointed quarry manager of the Maule Ojus Rock Co., Ojus, Fla.

JACOB T. BARRON, formerly general superintendent of generation of the Public Service Electric and Gas Co., Newark, N. J., has been appointed general manager of the electric department of that company.

WILLIAM R. LYON, who has been in the System Operation Office of the Pennsylvania Power and Light Co. at Hazleton, Pa., recently resigned to go with the Products Protection Corporation of New Haven, Conn.

H. H. ROGGE has recently been selected by the Westinghouse Electric International Company to be special representative to the Philippine Islands. Mr. Rogge's territory will also include the Dutch East Indies, the Malay Peninsula, and Siam.

HERBERT S. SANDS, Vice-President of the A. I. E. E. for District No. 6 and manager of the industrial division of the Westinghouse Electric & Manufacturing Co. at Denver, has had the degree of Electrical Engineer conferred upon him by the University of Colorado.

HERMAN J. B. SCHARNBERG, formerly Chief Engineer of the Sugar Estates of Oriente, Inc., and Associated Companies, is now Chief Engineer of the Compania Azucarera Vertientes, Central Vertientes, Camaguey, Cuba. Mr. Scharnberg was elected a Life Fellow of the Royal Society of Arts last year.

IRVING E. BROOKE, formerly of Muir and Brooke, has opened an office at 1211 Security Bldg., 189 West Madison St., Chicago, for the practise of general engineering: design, supervision, investigation, and reports. He will specialize in power plants, heating, ventilating, plumbing and wiring systems, and mechanical equipment.

Obituary

Clifford Gray Linnell, born August 22, 1891, died July 2, 1926, after a short illness. Mr. Linnell joined the Institute in 1915. He was educated in the Brownville schools and later attended Clarkson College at Potsdam, N. Y. In 1913 he was given charge of the electrical and mechanical work for a large Massachusetts plant, but in 1915 joined the Aluminum Company of America, Massena, New York; he also spent some time with the Duquesne Light Company at Pittsburgh, Pa. In 1925 he resigned from the Duquesne Light Company to identify himself with the Westchester Lighting Company at Mount Vernon, New York, with which he was connected at the time of his death. He was chief of the Distribution Department, and valued for his diligent and capable service.

Henry Knox McIntyre, for seventeen years connected with the Electrical Department of the North Carolina State College,

and Professor of Electrical Application, died recently in the South. Professor McIntyre was a native of New York City,—born here April 25, 1877. He attended Lyon's Collegiate Institute and entered Columbia University, taking the regular four years' course in Electrical Engineering and obtaining his E. E. degree in 1899. He was first employed in the Testing Department of the Sprague Electric Co., of Bloomfield, N. J., but left them to enter the Engineering Department of the New York Telephone Company, where he did worthy work in their Research Department. One of the developments in which he assisted was the Gray Telautograph. Of recent years, he has been active in the development of electrometallurgical processes adaptable to the mineral resources of North Carolina. Professor McIntyre joined the Institute in 1902. He was a member, also, of the American Electrochemical Society.

Addresses Wanted

A list of members whose mail has been returned by the postal authorities is given below, together with the addresses as they now appear on the Institute records. Any member knowing the present address of any of these members is requested to communicate with the Secretary, at 33 West 39th St., New York, N. Y.

All members are urged to notify the Institute Headquarters promptly of any change in mailing or business address, thus relieving the member of needless annoyance, and also assuring the prompt delivery of Institute mail, the accuracy of our mailing records, and the elimination of unnecessary expense for postage and clerical work.

1.—A. F. Buckley, 211 Sherman Ave., New York, N. Y.
2.—S. G. Guth, 419 Hampton Ave., Wilkinsburg, Pa.
3.—A. R. Henry, 20 St. Nicholas St., Montreal, Que., Can.
4.—M. E. Johnson, 133 Ardsley Road, Schenectady, N. Y.
5.—A. G. Corbin, 753 Crescent Ave., Buffalo, N. Y.
6.—D. F. McConnell, 402 N. Highland Ave., Pittsburgh, Pa.
7.—J. P. Ortiz, N. Y. Edison Co., 23rd St. & 4th Ave., New York, N. Y.
8.—I. T. Roberts, 2355 Prarie Ave., Evanston, Ill.

Engineering Societies Employment Service

Under joint management of the national societies of Civil, Mining, Mechanical and Electrical Engineers cooperating with the Western Society of Engineers. The service is available only to their membership, and is maintained as a cooperative bureau by contributions from the societies and their individual members who are directly benefited.

Offices:—33 West 39th St., New York, N. Y.,—W. V. Brown, Manager.
53 West Jackson Blv'de., Room 1736, Chicago, Ill., A. K. Krauser, Manager.
57 Post St., San Francisco, Calif., N. D. Cook, Manager.

MEN AVAILABLE.—Brief announcements will be published without charge but will not be repeated except upon requests received after an interval of one month. Names and records will remain in the active files of the bureau for a period of three months and are renewable upon request. Notices for this Department should be addressed to ***EMPLOYMENT SERVICE, 33 West 39th Street, New York City,*** *and should be received prior to the 15th of the month.*

OPPORTUNITIES.—A Bulletin of engineering positions available is published weekly and is available to members of the Societies concerned at a subscription rate of $3 per quarter, or $10 per annum, payable in advance. Positions not filled promptly as a result of publication in the Bulletin may be announced herein, as formerly.

VOLUNTARY CONTRIBUTIONS.—Members obtaining positions through the medium of this service are invited to cooperate with the Societies in the financing of the work by nominal contributions made within thirty days after placement, on the basis of $10 for all positions paying a salary of $2000 or less per annum; $10 plus one per cent of all amounts in excess of $2000 per annum; temporary positions (of one month or less) three per cent of total salary received. The income contributed by the members, together with the finances appropriated by the four societies named above, will it is hoped, be sufficient not only to maintain, but to increase and extend the service.

REPLIES TO ANNOUNCEMENTS.—Replies to announcements published herein or in the Bulletin, should be addressed to the key number indicated in each case, with a two cent stamp attached for reforwarding, and forwarded to the Employment Service as above. Replies received by the bureau after the positions to which they refer have been filled will not be forwarded.

POSITIONS OPEN

DISTRIBUTION ENGINEERS, technically trained and preferably with one or more years' experience with overhead or underground distribution or both. The work covers the engineering design, layout and estimate of costs of distribution systems, for a group of large power companies. Opportunity. Apply by letter with full particulars regarding past experience, salary wanted, date when available, and references. Location, Middlewest. X-453C.

GRADUATE ELECTRICAL ENGINEER, experienced in small electric motors, to establish sales department with company manufacturing electric appliances. Opportunity. Apply by letter with full details of age, past employment and salary, and lowest salary to start. Location, Middlewest. X-117.

ASSISTANT ELECTRICAL ENGINEER, 35-40, to take charge of drawing room. Experience in the design, construction and operation of power plant, substation and transmission line equipment. Switches and switchboard design experience essential. Married man preferred. Salary $3600-$4000. Apply by letter only. Headquarters, Philadelphia. X-584C.S.

ASSISTANT INSTRUCTOR in applied electricity and electrical machinery for large technical school. Apply by letter giving education, experience, age, religion and salary desired. Opportunity. Location, East. X-606.

MEN AVAILABLE

ELECTRICAL GRADUATE of class 21/22, 25 years of age, single, four years of practical electrical experience in installation, maintenance and repair, including testing of electrical systems, machinery and their operation. C-1115.

GRADUATE ELECTRICAL ENGINEER, 26, single, three years' experience in construction and operation of mine and mill electrifications, desires position with concern manufacturing mine electrical appliances. C-1714.

ENGINEER, who has had fourteen years' experience in electrical engineering is available. A position of maintenance engineer or switchboard design, layout and power circuits' engineer, or engineer in charge of factory equipment is desired. The fourteen years' experience takes in one year test course, two years drafting on switchboard, floor layouts, etc., three years as an assistant foreman on factory maintenance of testing equipment and eight years as engineer in charge of all testing equipment. All of the above time was spent with the General Electric Company, Schenectady, New York. C-1649.

ASSISTANT TO VICE PRESIDENT of large, progressive electric utility company desires position of increased responsibility. Graduate electrical engineer with fifteen years' design, operating, executive training in public utility work, including three years with well known consulting firm. Present duties consist of acting as engineering consultant to vice president and handling capital improvement program, including engineering, job scheduling, budget control, miscellaneous management problems. B-754.

ELECTRICAL ENGINEER, 1926 graduate Colorado, 30, married, desires position with public utility or electrical contracting company. Nominal salary. Location preferred, West or Middlewest. C-1746.

PROFESSOR ELECTRICAL ENGINEERING, ten years of teaching experience covering all the regular and many specialized electrical courses. Contact with the industry has been broad and covers design, construction and application. Well acquainted with the educational needs of the engineering profession. Change desired because present position does not encourage research. B-7083.

MECHANICAL-ELECTRICAL GRADUATE ENGINEER, 25, single, extensive training with Westinghouse people and General Electric Com-

pany, Schenectady, New York, desires permanent position in locality of Boston with manufacturing concern or power plant, preferably in connection with generators and transmissions. Available on reasonable notice. C-1740.

MECHANICAL ELECTRICAL ENGINEER, married, eighteen years' experience covering General Electric test, substation and power station design and operation for steel and wire mills, electrical cable manufacturing and sales. Executive and industrial development ability. A-4652.

YOUNG UNIVERSITY PROFESSOR desires research laboratory position. Degrees E. E. and M. E. E. Nine months' experience in research laboratory of automotive equipment electrical company, four and one-half years' teaching experience in electrical engineering department. Has attended teachers' summer conference with Westinghouse. 31, married. C-1037.

INVESTIGATIONS, 40, single. Experienced engineer desires investigational work, preferably of electrical and mechanical laboratory research or development type. Ability tested in many ways. Reports on problems requiring originality and resourcefulness, and the supervision of others, most satisfactory. Location preferred, Middlewest. B-6273.

ELECTRICAL ENGINEER, technical graduate, married, twenty years' experience, ten with construction and public utility companies on design, construction and economic investigations of central, substation and factory installations, desires position with industrial plant, public utility or construction company. C-581.

ELECTRICAL ENGINEER, 28, single, with technical education. Five years' general electrical work, two years as assistant production manager in a manufacturing plant. Desires position in production or similar work where there is an opportunity to advance. Vicinity of New York preferred. Available immediately. B-8056.

PRODUCTION ENGINEER, A. I. E. E., 30, married, Engineering and Arts graduate; qualified by experience for Production Schedule, Budget or Valuation Engineering; 5 years Utility, four years' Industrial experience; prefer Managerial to strictly technical. Available Oct. 15, 1926. B-9676.

ELECTRICAL ENGINEER, . B. and M. S. degrees, 27, single. Experience—G. E. test course and three years with Transmission and Distribution Department of a large utility. Especially familiar with cables, transformers and distribution network problems. Connection with another utility or consulting firm on engineering and economic problems desired. Location preferred, south or east. C-1750.

UNIVERSITY GRADUATE, (1916), 35, single, Electrical and Mechanical Engineering, all-round experience, one year illumination tests, four years drafting and designing, especially automatic machinery; two years writing of technical reports and patent disclosures with patent drafting, mathematical computations. Besides English, speaks and writes three other languages. B-7214.

EXECUTIVE ELECTRICAL ENGINEER, 27, married, educated Canterbury College, now located with a prominent firm in New Zealand, handling all classes of Electrical plant, including heavy machinery and also household appliances, would like a change to U. S. A. Been accustomed to buying and price-fixing and also acting in a consulting capacity to clients requiring plant. Considerable experience in Public tendering. Available on short notice. Prepared to start at anything offering good chances of advancement. Would prefer West coast location. C-1763

FACTORY MANAGER OR ENGINEERING EXECUTIVE, 37, Technical Graduate 1911. Balanced experience in necessary branches leading to management includes shop apprenticeship, general engineering, production and management. Successful record shows cost reductions and abilities in analysis, invention, vision, and judgment. Fullest investigation of record and references invited. C-1776.

ELECTRICAL ENGINEER AND EXECUTIVE, 35, Married, 16 years' experience in operation, engineering and design of electrical apparatus. Has accomplished complicated design work. Has handled a large number of men. Desires position with manufacturing company as representative, sales engineer or responsible executive position. Has New York State Professional Engineer's license. C-1579.

COMMERCIAL ENGINEER, technical graduate, seven to eight years' experience in the public utility business on power and lighting sales, rates, engineering and operation. Desires connection with holding or management company of public utilities or with power company. Age 32, excellent health. Available on reasonable notice. B-9782.

ELECTRICAL & MECHANICAL ENGINEER, 24, single, graduate of Cornell, two years' experience in electrical plant, doing A. C. & D. C. assembly work, A. C. design, foundry work in connection with elevators, desires position, not particular about hours, work or location, would like position with plenty of work and good future, min. salary $160 a month. C-1769.

ELECTRICAL DESIGNER, 30, single, technical graduate, three years' practical experience in power station operation and factory, six years design electrical machinery and transformers, power and substations. Desires position with electrical manufacturing concern or power company offering opportunities for advancement. Available after two weeks' notice. Location, anywhere. C-10.

ELECTRICAL ENGINEER, 34, married, twelve years' experience in the design and operation of generating stations, substations, and transmission systems, eight years with large public utility, and four with industrial corporations. Recent extensive experience on automatic substations and supervisory control. Available in one month. Location, any, but North Central States preferred. C-635.

RECENT GRADUATE IN ELECTRICAL ENGINEERING, desires opportunity for foreign service. Testing and research experience. Position need not be strictly technical. Available within reasonable notice. C-348.

GENERAL EXECUTIVE, 43, married, mechanical and electrical engineer; five years manufacturing and engineering; ten years' commercial, five years' financial experience. Three years in charge of industrial re-organizations for large financial institution; keen analyst; good organizer. Available at once. A-4098.

ENGINEER, age 30, single, graduate E. E. with 7 years' experience in design and construction of Central stations, substations, and industrial Plants; also, distribution, overhead and underground. Available immediately. Location, immaterial. B-4662.

MEMBERSHIP — Applications, Elections, Transfers, Etc.

ASSOCIATES ELECTED AUGUST 10, 1926

AIYANGAR, SRINIVASA RAJAGOPALA, Managing Engineer, Sri Brahmavidyambal Electric Supply Corp., Ltd., Ramachandrapuram, Trichinopoly Dist., S. India.

ALLEN, ROBERT LIVINGSTON, Chief Engineer, Archbold-Brady Co., Greeneway Ave., Syracuse, N. Y.

BENNETT, R. S., Sales & Engineering, General Electric Co., 215 W. 3rd St., Cincinnati, Ohio.

BHUSARI, VASUDEO GANESH, Lecturer, V. J. Technical Institute, Matunga, Bombay, India.

*BLAKE, FRANK JEROME, Engineer, Outside Distribution Properties, Public Service Co. of Colorado, Gas & Elec. Bldg., Denver, Colo.

BOWEN, WILLIAM EARL, Asst. Valuation Engineer, Great Western Power Co., 375 Sutter St., San Francisco; res., Oakland, Calif.

BRAMBLETT, PAUL FRANCIS, Division Foreman, Northwestern Light & Power Co., Sibley, Iowa.

BRANSON, ALBERT KEMPER, Operator, Great Western Power Co. of California, 8425 Foothill Blvd., Oakland; for mail, Caribou, Plumas Co., Calif.

BROCKETT, NORWOOD W., Director of Public Relations, Puget Sound Power & Light Co., 860 Stuart Bldg., Seattle, Wash.

BURROW, PERCY, Supt. of Power Plant, Puget Sound Power & Light Co., Dryden, Wash.

BUTOW, F. W. C., Foreman, Electric Dept., Pacific Coast Steel Co., South San Francisco; res., San Bruno, Calif.

BUTTERWORTH, RUSSELL IRVIN, General Supt., Bristol Gas & Electric Co., Bristol, Tenn.

CAPRIN, VLADIMIR I., Electrification Dept., Illinois Central Railroad, Chicago, Ill.

CARRASCO-ZANINI, JUAN, Electrical Engineer, Mexican Light & Power Co., Donceles No. 80, Mexico, D. F., Mex.

CECCHETTI, FELIX, Testing Dept., General Electric Co., Erie Blvd., Schenectady, N. Y.

CHANG, ZUNG ZUE, Engineer, Engg. Dept., Westinghouse Elec. & Mfg. Co., Sharon, Pa.

CUNNINGHAM, KENNETH GEORGE, Trunk Engineer, Ohio Bell Telephone Co., 5300 Prospect Ave., Cleveland, Ohio.

CURTIS, HERBERT CRICHTON, Development Dept., Cutler-Hammer Mfg. Co., Milwaukee, Wis.

de LIMA, CLARENCE A., Radio Engineer, Westinghouse Electric International Co., Mexico D. F., Mex.

de MULINEN, EGBERT F. H., Electrical Engineer, American Brown Boveri Electric Corp., Camden; res., Haddon Heights, N. J.

DENNIS, EARLE M., Electrical Engineer, Bloedel Donovan Lumber Mills, Bellingham, Wash.

DICKINSON, ROBERT BIGLAND, Electrical Engineer, Engg. Dept., Duke Price Power Co., Ltd., Isle Maligne, Lake St. John, P. Q., Can.
DITESHEIM, GASTON J., Manager, Movado Co., 516 5th Ave., New York, N. Y.
DONALDSON, LESLIE JAMES, Asst. Engineer, Brown Boveri & Co., Ltd., Baden, Switzerland; for mail, Sydney, N. S. W., Aust.
DONOVAN, WALTER, Electrical Engineer, General Electric Co., Ltd., 6801 Glenwood Ave., Philadelphia, Pa.
DRAKE, RUSSEL ALONZO, Electrician's Mate, (3rd class), U. S. Navy, U. S. S. Arizona, San Francisco, Calif.
DUNKELBERG, PAUL R., Computor, Illinois Central Railroad Co., 109 E. Roosevelt Road, Chicago, Ill.
ENTEE, FRAMROZE DHUNJISHAW, Electrical Engineer, Century Mills, Parel, Bombay, India.
ESTRADA, JOSE FLORES, Asst. Electrical Engineer, Havana Central Railroad Co., Estacion Central, Havana, Cuba.
FOGG, LEIGH E., Cable Engineer, American Electrical Works, Phillipsdale, R. I.
GATTIKER, CARL H., Asst. Supt. of Construction, The New York Edison Co., 130 East 15th St., New York, N. Y.
GEARY, STEPHEN JOSEPH, Mains Supt., Municipal Electricity Dept., Christchurch, N. Z.
GILBERT, C. F., Chief Draftsman, Canadian Crocker-Wheeler Co., Ltd., St. Catharines, Ont., Can.
GILROY, JOHN R., Switchboard Operator, Commonwealth Edison Co., 25th & Quarry Sts., Chicago, Ill.
GRAY, WILBUR S., Draftsman, Stone & Webster, Inc., 147 Milk St., Boston, Mass.
GRONVOLD, INGVALD JULIAN, Electrician, Neil Electric Co., Isleton, Calif.
HAENTJENS, OTTO, President, Barrett, Haetjens & Co., Hazleton, Pa.
*HAMMOND, ROBERT JAMES, Supervising Engineer, The Pacific Tel. & Tel. Co., 1900 S. Grand, Los Angeles, Calif.
*HASTINGS, DONALD FRANCIS, Tester, Rossiter, Tyler & McDonell, 136 Liberty St., New York, N. Y.
HEINTZ, WILLIAM THEODOR, Sales Engineer, Automatic Electric Co., 427 Bourse Bldg., Philadelphia, Pa.
HEMSLEY, SYDNEY HENRICK, Power Transformer Designer, Messrs. Ferranti, Ltd., Hollinwood; for mail, Oldham, Lancashire, Eng.
HERNE, WALLACE WENDELL, Asst. Valuation Engineer, Great Western Power Co., San Francisco, Calif.
HILDEBRANDT, JOHN LAWRENCE, Research & Test Dept., Consolidated Gas, Electric Light & Power Co., Baltimore; res., Catonsville, Md.
HUDD, ALFRED ERNEST, Consulting Engineer, Automatic Electric Inc., 1033 W. Van Buren St., Chicago, Ill.
*HUMPHRIES, POWELL HORNER, Asst. in Elec. Engg. Dept., Harvard University, Pierce Hall, Cambridge; res., West Roxbury, Boston 32, Mass.
IRWIN, JAMES E., Elec. Constr. Foreman, Chile Exploration Co., Chuquicamata, Chile, So. Amer.
ISCHINGER, ALFRED ERNST, In charge of Engg. Dept., Joshua R. H. Potts, 929 Chestnut St., Philadelphia, Pa.
JAYNE, JOHN KENNON, Electric Representative, Autocar Co., 930 Bedford Ave., Brooklyn; res., New York, N. Y.
KEEFER, JOHN, Electrician, Pacific Coast Steel Co., South San Francisco, Calif.
KOHLHEPP, WILLIAM SAMUEL, Equipment Engineer, Cumberland Tel. & Tel. Co., Louisville, Ky.
LARKIN, JOHN J., Supt. of Signals, Brooklyn-Manhattan Transit Corp., 85 Clinton St., Brooklyn; res., Jamaica, N. Y.
LEON, CONSTANTINE, Jr., Electrical Engineer, Dept. of Electricity, Havana Central Railroad Co., Estacion Central, Havana, Cuba.
LESSING, OTTO, Cadet Engineer, Counties Gas & Electric Co., Penn & Markley Sts., Norristown, Pa.
LYDON, REGINALD JAMES BUNDY, Senior Instructor, Elec. Engg. Branch, Central Technical College, Brisbane, Queensland, Aust.
MacKAY, ALBERT TUTTLE, Inspector, Western Electric Co., 379 Summer St., Boston; res., Roslindale, Mass.
MacCORMICK, CHARLES M. C., Student Engineer, General Electric Co., Schenectady, N. Y.
*MADER, CLARENCE EDWARD, Student, Lewis Institute, 7704 Crandon Ave., Chicago, Ill.
MAHNKE, KURT, Draftsman, Pennsylvania Power & Light Co., 324 West St., Williamsport, Pa.
MAHONEY, JAMES FRANCIS, General Foreman, Brooklyn Edison Co., 14 Rockwell Place, Brooklyn, N. Y.
MARQUARDT, MAX, Electrician, 316 Rutherford Blvd., Passaic, N. J.
MARTINOV, VLADIMIR, Manager, Central & Substation Dept., State Electrotechnical Trust, 56 Prosp. of Oct. 25th, Leningrad, Russia.
MENDENHALL, WALKER HAMILTON, Asst. Engineer, Relay Dept., West Penn Power Co., 14 Wood St., Pittsburgh, Pa.
MERRITT, DAVID FRANKLIN, Electrical Mechanic, Famous Players Lasky Co., 1520 Vine St., Hollywood; res., Sherman, Calif.
METCALF, JAMES IRWIN, Reports Dept., Day & Zimmermann, Inc., 1600 Walnut St., Philadelphia, Pa., res., Bronxville, N. Y.
MILLER, NORBERT O. C., Owner, Schwall Electric Works, 429 E. Channel St., Stockton, Calif.
MOITINHO, RUBEN, Electrical Engineer-Government Inspector, Electrical Public Services; Secretaria Geral do Estado do Rio de Janeiro, Nictheroy, Brazil, So. America.
NAKAMURA, HIROSHI, Asst. Electrical Engineer, Toho Electric Power Co., Kaijo Bldg., Tokjo, Japan; for mail, Wilkinsburg, Pa.
PALLONJI, D., Managing Engineer & Proprietor, Marine Electrical Engineering Works, Examiner Press Bldg., Dalal St., Fort Bombay, India.
PALM, I. ROBERT, Squad Man, Sargent & Lundy, 1407 Edison Bldg., Chicago, Ill.
PATRICK, RICHARD A., Electrical Mechanic, Truckee River Power Co., 21 Front St., Reno, Nev.
PINCKERT, WALTER F., Draftsman, Pacific Gas & Electric Co., San Francisco, Calif.
POUGY, ADHERBAL M., Chief Electrical Engineer, Cia Docas de Santos, Seccao Electrica, Santos, Brazil, So. Amer.
RAYMENT, EDWARD GEORGE, Foreman, Bethlehem Steel Co., Dock Central, La Plata, Arg. Rep., S. Amer.
REID, ALEXANDER, Production Engineer, Canadian Crocker-Wheeler Co., Ltd., St. Catharines, Ont., Can.
REID, MATTHEW, Resident Electrical Engineer, St. George County Council, Kogarah, Sydney, N. S. W., Aust.
ROGERS, FREDERICK HELME, Student Apprentice, Elec. Div., Consolidated Gas, Electric Light & Power Co., Baltimore, Md.
ROSADO, ANTONIO, Asst. Electrical Engineer, Havana Electric Railway, Light & Power Co., Monto No. 1, Habana, Cuba.
RUDORFF, DAGOBERT WILLIAM, Mechanical Asst. Engineer, Mexican Light & Power Co., Ltd., Necaxa, Puebla, Mex.
SANCHEZ, URBANO C., Supt., Distribution & Meter Dept., Compania de Electricidad de Merida, Yucatan, Mex.
SCHARF, PAUL BERNARD, Instructor, Mathematics & Science Dept., Goodyear Industrial University, Akron, Ohio.
SCHIFREEN, CLEMENT S., Electrical Designer, Philadelphia Electric Co., 1035 Chestnut St., Philadelphia, Pa.
SCHLEGEL, ROY DAVIS, Asst. Supt., Conduit Div., Potomac Electric Power Co., 213 14th St., N. W., Washington, D. C.
SHARROCK, LEWIS LEE, Electrical Draftsman, St. Lawrence County Utilities, Inc. Potsdam, N. Y.
SKELTON, WILLIAM JOSEPH, Supervisor, Wisconsin Telephone Co., 1401 Clybourn St., Milwaukee, Wis.
SKINNER, ROBERT W., Construction Dept., Louisville Gas & Electric Co., Louisville, Ky.
STAGGS, NEWMAN K., Telephone Engineer & Contractor, The Telephone Engineering & Equipment Co., 216 Douglas Bldg., Seattle, Wash.
STEEL, EDWARD T., District Manager, Puget Sound Power & Light Co., Bremerton, Wash.
STEINMETZ, WILLIAM CLYDE, Supervisor, Telephone & Telegraph, The Alaska Railroad, Anchorage, Alaska.
SWANSON, EARL R., Division Engineer, Wisconsin Power & Light Co., Fond du Lac, Wis.
SYLVESTER, FRANK EDWIN, Supt., Substations, Great Western Power Co., 3729 Park Blvd., Oakland; res., Alameda, Calif.
TANDBERG, LEONARD G., Salesman, Wagner Electric Corp., 318 W. 15th St., Los Angeles, Calif.
TAYLOR, FRANK WARBURTON, Transformer Designer, Ferranti, Ltd., Hollinwood; res., Oldham, Lancashire, Eng.
TERHUNE, WALLACE IRVING, Engineering Assistant, Public Service Production Co., 80 Park Place, Newark, N. J.
THOMPSON, EUGENE PERCIVAL, Chief Electrical Engineer, St. George County Council, Kogarah, Sydney, Aust.
TILLQUIST, DAVID, Powerman, New York Telephone Co., 230 W. 36th St., New York, N. Y.
TORRES, SALVADOR EVARISTO, Foreman, Electrical Dept., Transcontinental Petroleum Co., La Barra Refinery, Tampico, Mexico.
VAN ETTEN, FRANK C., Manufacturers' Representative, 600 Joyce Realty Bldg., Columbus, Ohio; res., Chicago, Ill.
VAN WHY, FORBES WILLIAM, Radio Engineer-in-charge, Pasadena Star-News, 525 E. Colorado St., Pasadena, Calif.
VARLEY, HARRY, Managing Director, The Electric Motor & Stove Hiring Co., Ltd., Sweet St., Leeds, Yorkshire, Eng.
VONSOVICH, LEO J., Junior Engineer, Valuation Dept., Great Western Power Co. of California, Berkeley, Calif.
WALSH, FRANK, Supt. of Power, N. E. Dist., Puget Sound Power & Light Co., 3030 Colby St., Everett, Wash.
WARREN, PICKETT L., Salesman, Ohio Brass Co., 1714 Fisher Bldg., Chicago, Ill.
WATSON, STEWART CLARK, Switchboard Engineer, Switchboard Engg. Dept., Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa.
WATTS, WILLIAM EWART GLADSTONE, Elec. Engineer in charge of Colliery Elec. Plant, Luscar Collieries, Luscar via Edmonton, Alta., Can.
WAY, ROBERT S., Power Engineer, Worcester Suburban Electric Co., Main St., Uxbridge, Mass.
WEAVER, R. A., Plant Engineer, Cincinnati & Suburban Bell Telephone Co., 225 E. 40th St., Cincinnati, Ohio.
WELLS, DONALD V., Division Manager, Northwestern Light & Power Co., Sibley, Iowa.

WHISENAND, OMER BURTON, Chief Electrician, Citizens Gas Co., 47 S. Pennsylvania St., Indianapolis, Ind.

WOLLEBAK, THOR, Designing Engineer, Delta Star Electric Co., 2433 Fulton St., Chicago, Ill.

Total 114

*Formerly Enrolled Students.

ASSOCIATES REELECTED AUGUST 10, 1926

BOYERE, EMERY E., Electrical Specialist, Small Motor Applications, 708 State St., Erie, Pa.

REHWALDT, ARTHUR W., Electrical Engineer, Sargent & Lundy, 72 W. Adams St., Chicago, Ill.

STOTLER, EDWIN JOHN, Elec. Engg., Sears, Roebuck & Co., 11 Astor St., Newark, N. J.; for mail, Chicago, Ill.

MEMBERS ELECTED AUGUST 10, 1926

BUTLER, M. BAYORD, Jr., Electrical Engineer, American Chain Co., Bridgeport; res. Waterbury, Conn.

JONES, REGINALD ELSDON, Asst. Engineer, Elec. Engg. Dept., Hydro-Electric Power Commission of Ontario, 190 University Ave., Toronto, Ont., Can.

SCHUMAN, JOSEPH HENRY, Engineer, Construction Bureau, The Edison Electric Illuminating Co. of Boston, 39 Boylston St., Boston, Mass.

THOMPSON, CHARLES SCOTT, Consulting Engineer, 1207 Medical Arts Bldg., Oklahoma City, Okla.

WESTBYE, JOHN, Designer, Gibbs & Hill, Pennsylvania Station, New York; res., Brooklyn, N. Y.

WHITE, WILLIAM COLLINS, Div. Transmission Engineer, Cumberland Tel. & Tel. Co., Louisville, Ky.

TRANSFERRED TO GRADE OF FELLOW AUGUST 10, 1926

McQUARRIE, JAMES L., Chief Engineer, International Standard Electric Corp., London, England.

TRANSFERRED TO GRADE OF MEMBER AUGUST 10, 1926

NORRIS, ERIC D. T., Technical Electrical Engineer, Ferranti Ltd., Hollinwood, Lancashire, England.

THOMAS, HERBERT P., Chief Engineer, Southland Electric Power Board, Invercargill, N. Z.

RECOMMENDED FOR TRANSFER

The Board of Examiners, at its meeting held July 26, 1926, recommended the following members for transfer to the grade of membership indicated. Any objection to these transfers should be filed at once with the National Secretary.

To Grade of Member

ANDREWS, HARDAGE L., Assistant Engineer, Railway Engineering Dept., General Electric Co., Schenectady, N. Y.

ANDREWS, JOSEPH F., American Tel. & Tel. Co., New York, N. Y.

AUTY, CLARENCE, Assistant Electrical Engineer, C. H. Tenney & Co., Boston, Mass.

BALE, LAWRENCE D., Supt. of Power, Cleveland Railway Co., Cleveland, Ohio.

BATES, LOUIS I., Engineer of Electric Distribution, Bronx Gas & Electric Co., New York, N. Y.

BENTON, JOHN R., Professor of Physics and Electrical Engineering, University of Florida, Gainesville, Fla.

BETTANNIER, EUGENE L., Electrical Engineer, Municipal Light & Power Department, Pasadena, Calif.

BOWMAN, HAROLD L., Service Engineer, Westinghouse Electric & Mfg. Co., New York, N. Y.

BROWN, HUGH A., Assistant Professor of Electrical Engineering, University of Illinois, Urbana, Ill.

CAVE, JOSEPH, Electrical Superintendent, Canadian General Electric Co., Toronto, Ont.

DREW, ERNEST C., Assistant Engineer, Bell Tel. Co. of Pennsylvania, Philadelphia, Pa.

DUBOSE, McNEELY, Electrical Superintendent, Aluminum Co. of Canada, Ltd., Arvida, Que.

FISHEL, ANTHONY D., Sales and Electrical Engineer, A. D. Fishel Co., Cleveland, Ohio.

FROM, OWEN C., Telephone Systems Engineer, Bell Telephone Laboratories, Inc., New York, N. Y.

GILLILAN, P. M., Railway Engineer, General Electric Co., Schenectady, N. Y.

GRAY, ROBERT, L., Electrical Engineer, Tararua Electric Power Board, Eketahuna, New Zealand.

HAMILTON, HAROLD C., Asst. Supt., Standardizing & Testing Dept., Edison Electric Illuminating Co. of Boston, Boston, Mass.

HART, R. PHILIP, Manager, Cazenovia Electric and Cazenovia Tel. Corp., Cazenovia, N. Y.

HENLINE, HENRY H., Associate Professor of Electrical Engineering, Stanford University, Stanford University, Calif.

HIGHT, WILLIAM R., Assistant Compass Engineer, Sperry Gyroscope Co., Brooklyn, N. Y.

JOHNSON, FRANCIS E., Professor of Electrical Engineering, University of Kansas, Lawrence, Kans.

KONGSTED, L. P., Research Engineer, American Bosch Magneto Corp., Springfield, Mass.

KURTZ, EDWIN, Professor and Head, Dept. of Electrical Engineering, Oklahoma A. & M. College, Stillwater, Okla.

LaROQUE, HAROLD B., Switchboard Engineering Dept., General Electric Co., Schenectady, N. Y.

McMILLAN, FRED O., Associate Professor of Electrical Engineering, Oregon State Agricultural College, Corvallis, Ore.

MICHENER, HAROLD, Asst. to Executive Engineer, Southern California Edison Co., Los Angeles, Calif.

MILLER, JOHN H., Chief Electrical Engineer, Jewell Electrical Instrument Co., Chicago, Ill.

MONG, CLIFFORD E., Engineer, Pacific Tel. & Tel. Co., Seattle, Wash.

MONROE, WENDELL P., Assistant Engineer, Illinois Central Railroad, Chicago, Ill.

MORROW, ALLEN, Department Head, Power Department, Standard Oil Co. of California, Richmond, Calif.

NETHERCUT, DONALD W., Distribution Supt., Ohio Public Service Co., Sandusky, Ohio.

NYMAN, ALEXANDER, Director, Radio Patents Corp., New York, N. Y.

O'NEAL, J. P., Westinghouse Electric & Mfg. Co., Sharon, Pa.

PACKARD, ANSEL A., Division Manager, Connecticut Power Co., Middletown, Conn.

PETERS, LEO J., Asst. Professor of Electrical Engineering, University of Wisconsin, Madison, Wis.

POTTS, LOUIS M., Electrical Engineer, Bell Telephone Laboratories, Inc., New York, N. Y.

READ, WALTER V., Telephone Engineer, American Tel & Tel. Co., New York, N. Y.

RODEY, BERNARD S., Jr., Engineer Accountant, United Electric Light & Power Co., New York, N. Y.

RYAN, FRANCIS M., Radio Engineer, Bell Tel. Laboratories, Inc., New York, N. Y.

SCHENCK, CHESTER, Materials Engineer, Elec. Engg. Dept., Commonwealth Power Corp., Jackson, Mich.

SHACKELFORD, BENJAMIN E., Chief Physicist, Westinghouse Lamp Co., Bloomfield, N. J.

THOMAS, RALPH L., Asst. to General Superintendent, Pennsylvania Water & Power Co., Baltimore, Md.

WORRALL, ROBERT H., Radio Engineer, U. S. Naval Research Laboratory, Bellevue, D. C.

APPLICATIONS FOR ELECTION

Applications have been received by the Secretary from the following candidates for election to membership in the Institute. Unless otherwise indicated, the applicant has applied for admission as an Associate. If the applicant has applied for direct admission to a higher grade than Associate, the grade follows immediately after the name. Any member objecting to the election of any of these candidates should so inform the Secretary before September 30, 1926.

Atkins, G. E., New England Tel & Tel Co., Boston, Mass.; for mail, New York, N. Y.

Atkinson, C. S., Shawinigan Water & Power Co., Montreal, P. Q., Can.

Bradt, A. W., (Member), Hamilton Hydro Electric System, Hamilton, Ont., Can.

Brandt, R., General Electric Co., Schenectady, N. Y.

Briggs, M. J., Stone & Webster, Tampa, Fla.

Brown, W. W., (Member), General Electric Co., Schenectady N. Y.

Campbell, I. S., Ohio Northern University, Ada, Ohio

Carter, T. E., Florida Power & Light Co., Miami, Fla.

Cosgrove, J. M., The Meaker Co., Chicago, Ill.

Cullwick, E. G., Canadian General Electric Co., Peterboro, Ont., Can.

Daniels, C. C., The Montana Power Co., Columbus, Mont.

de la Macorra, Jr., J., San Rafael Paper Co., Mexico City, Mex.

Duré, H. J. Edison Elec. Ill. Co. of Boston, Roxbury, Mass.

Finigan, W., Supt., Federal Trust & Clinton Bldg., Newark, N. J.

Fitzgerald, E. B., 28 Meridian St., Greenfield, Mass.

Foley, J. R., Appalachian Electric Power Co., Roanoke, Va.

Gatternigg, R., (Member), Pacific Portland Cement Cons. Co., Cement, Calif.

Gaylord, C. E., New York Telephone Co., Buffalo, N. Y.

Hall, H. M., American Copper Products Corp., New York, N. Y.
(Applicant for re-election.)

Huffman, G. A., New England Tel & Tel. Co., Boston, Mass.

Kempf, R. E., Pacific Oil & Lead Works, San Francisco, Calif.

Lucro, E. N., Public Service Production Co., Newark, N. J.

Lundgreen, S. O. G., General Electric Co., West Philadelphia, Pa.

Maiman, A., 2946 California St., San Francisco, Calif.

Max, C., Central Railroad Co. of New Jersey, Elizabethport, N. J.

Mayor, R., Jr., General Electric Co., Havana, Cuba

McLean, M. M. M., General Electric Co., West Lynn, Mass.

Miller, W. C., (Member), The Detroit Edison Co., Detroit, Mich.

Remaly, C. E., The R. Thomas & Sons Co., East Liverpool, Ohio

Remington, H. N., International Creosoting & Construction Co., Chicago, Ill.

Rienstra, A. R., Bell Telephone Laboratories, Inc., New York, N. Y.

Scanavino, S. A., Pacific Gas & Electric Co., San Francisco, Calif.

Schuler, Charles E., Asst. Chief Engineer, Elec. Dept., International Derrick & Equipment Co., Michigan & Buttles Aves., Columbus, Ohio

Stockwell, H. L., Tampa Electric Co., Tampa, Fla.

Storm, S. B., Marine Electric Co., Louisville, Ky.

Tefft, W. W., (Member), Commonwealth Power Corp., Jackson, Mich.
Wagner, H. H., Automatic Electric Co., Inc., Chicago, Ill.
Weissman, L. Hudson & Manhattan R. R. Co., New York, N. Y.
Wilson, H. R., Philadelphia Electric Co., Philadelphia, Pa.
Zuckerman, H., Wholesale Radio Equipment Co., New York, N. Y.
Total 40.

Foreign

Braudé, A. N., India Rubber Gutta-Percha & Telegraph Works Co., Ltd., London, Eng.
Campbell, F. W., Nottingham Corp., Nottingham, Eng.
Orbell, R. J., Thames Valley Power Board, Te Aroha, N. Z.
Peterson, A. W., Porto Rico Tel. Co., San Juan, Porto Rico
Poyitt, D. G., Municipal Council of Sydney, Sydney, N. S. W., Aust.
Stowers-Crowley, C. M. (Member), Opunake Elec. Pr. Board, Opunake, N. Z.
Sutherland, K., State Electricity Comm. of Victoria, Melbourne, Aust.
Total 7.

STUDENTS ENROLLED

Buckley, Chester F. Mass. Institute of Tech.
Feldman, Nikola, University of Latvia
Fluskey, Robert J., New York University
Gordon, Nathan B., Northeastern University
Lissner, Earle D., Massachusetts Inst. of Tech.
MacDonald, Hugh C., Northeastern University
Roake, Wilber C., Stevens Inst. of Tech.
Sanborn, John W., Mass. Inst. of Tech.
Veltre, Frank E. Jr., Georgia School of Tech.
Wheeler, Kimball L., Mass. Inst of Tech.
Total 10.

Officers A. I. E. E. 1926-1927

PRESIDENT

(Term expires July 31, 1927)
C. C. CHESNEY

JUNIOR PAST PRESIDENTS

(Term expires July 31, 1927) FARLEY OSGOOD
(Term expires July 31, 1928) M. I. PUPIN

VICE-PRESIDENTS

(Terms expire July 31, 1927)
P. M. DOWNING (District No. 8)
HERBERT S. SANDS (District No. 6)
W. E. MITCHELL (District No. 4)
ARTHUR G. PIERCE (District No. 2)
W. P. DOBSON (District No. 10)

(Terms expire July 31, 1928)
H. M. HOBART (District No. 1)
B. G. JAMIESON (District No. 5)
GEORGE L. KNIGHT (District No. 3)
H. H. SCHOOLFIELD (District No. 9)
A. E. BETTIS (District No. 7)

MANAGERS

(Terms expire July 31, 1927)
W. M. McCONAHEY
W. K. VANDERPOEL
H. P. CHARLESWORTH

(Terms expire July 31, 1928)
JOHN B. WHITEHEAD
J. M. BRYANT
E. B. MERRIAM

(Terms expire July 31, 1929)
M. M. FOWLER
H. A. KIDDER
E. C. STONE

(Terms expire July 31, 1930)
I. E. MOULTROP
H. C. DON CARLOS
F. J. CHESTERMAN

NATIONAL TREASURER — **NATIONAL SECRETARY**

(Terms expire July 31, 1927)
GEORGE A. HAMILTON — F. L. HUTCHINSON

HONORARY SECRETARY

RALPH W. POPE

GENERAL COUNSEL

PARKER & AARON
30 Broad Street, New York

PAST PRESIDENTS—1884-1926

*Norvin Green, 1884-5-6.
*Franklin L. Pope, 1886-7.
*T. Commerford Martin, 1887-8.
Edward Weston, 1888-9.
Elihu Thomson, 1889-90.
*William A. Anthony, 1890-91.
*Alexander Graham Bell, 1891-2.
Frank Julian Sprague, 1892-3.
*Edwin J. Houston, 1893-4-5.
*Louis Duncan, 1895-6-7.
*Francis Bacon Crocker, 1897-8.
A. E. Kennelly, 1898-1900.
*Carl Hering, 1900-1.
*Charles P. Steinmetz, 1901-2
Charles F. Scott, 1902-3.

(Terms expire July 31, 1930)

George Gibbs, Samuel Insull, Ralph D. Mershon.

(Terms expire July 31, 1931)

John W. Howell, L. F. Morehouse, David B. Rushmore.

Elected by the Board of Directors from its own membership for term of two years.

(Terms expire July 31, 1927)

W. P. Dobson, Farley Osgood, A. G. Pierce.

(Terms expire July 31, 1928)

B. G. Jamieson, H. A. Kidder, G. L. Knight.

Ex-Officio

C. C. Chesney, President, George A. Hamilton, National Treasurer.
F. L. Hutchinson, National Secretary.

COMMITTEE ON CODE OF PRINCIPLES OF PROFESSIONAL CONDUCT

John W. Lieb, Chairman, 124 E. 15th St., New York, N. Y.

A. H. Babcock,	R. D. Mershon,	Harris J. Ryan,
G. Paccioli,	L. F. Morehouse,	C. E. Skinner.

COMMITTEE ON AWARD OF INSTITUTE PRIZES

E. B. Meyer, Chairman, 80 Park Place, Newark, N. J.

L. F. Morehouse, John B. Whitehead.

COMMITTEE ON AWARD OF COLUMBIA UNIVERSITY SCHOLARSHIPS

W. I. Slichter, Chairman, Columbia University, New York, N. Y.

Francis Blossom, H. C. Carpenter.

COMMITTEE ON SAFETY CODES

John Price Jackson, Chairman, N. Y. Edison Co., 130 E. 15th St., New York, N. Y.

F. A. Barron,	H. B. Gear,	Farley Osgood,
Philander Betts,	P. J. Howe,	George Quinan,
W. J. Canada,	L. C. Ilsley,	Joseph Sachs,
R. N. Conwell,	M. G. Lloyd,	H. R. Sargent,
J. V. B. Duer,	Ernest Lunn,	W. H. Sawyer,
J. C. Forsyth,	Wills Maclachlan,	M. L. Sindeband,
R. C. Fryer,	J. C. Martin,	Paul Spencer,
D. H. Gage,	J. E. Moore,	H. S. Warren.
	R. W. E. Moore,	

SPECIAL COMMITTEES

LICENSING OF ENGINEERS

Francis Blossom, Chairman, Sanderson & Porter, 52 William St., New York, N. Y.

H. W. Buck,	Gano Dunn,	E. W. Rice, Jr.
	L. E. Imlay,	

TECHNICAL ACTIVITIES

A. G. Pierce, Chairman, 1239 Guardian Building, Cleveland, Ohio

H. P. Charlesworth,	H. M. Hobart,	J. B. Whitehead.
	H. A. Kidder,	

TECHNICAL COMMITTEES

COMMUNICATION

H. P. Charlesworth, Chairman, 195 Broadway, New York, N. Y.

F. L. Baer,	D. H. Gage,	F. A. Raymond,
L. W. Chubb,	S. P. Grace,	Chester W. Rice,
J. L. Clarke,	P. J. Howe,	J. K. Roosevelt,
Charles E. Davies,	F. H. Kroger,	H. A. Shepard,
H. W. Drake,	Ray H. Manson,	J. F. Skirrow,
Major P. W. Evans,	R. D. Parker,	E. B. Tuttle,
R. D. Evans,	H. S. Phelps,	K. L. Wilkinson,
E. H. Everit,	Lt. Commdr. B. B. Ralston,	F. A. Wolff,
L. F. Fuller,		C. A. Wright.

EDUCATION

P. M. Lincoln, Chairman, Franklin Hall, Cornell University, Ithaca, N. Y.
R. E. Doherty, Vice-Chairman, Schenectady, N. Y.

C. A. Adams,	J. P. Jackson,	Harold B. Smith,
Edward Bennett,	John Mills,	R. W. Sorensen,
Nelson J. Darling,	H. H. Norris,	J. B. Whitehead,
Gano Dunn,	Harold Pender,	W. R. Whitney,
W. C. L. Eglin,	W. L. Robb,	W. E. Wickenden.

ELECTRICAL MACHINERY

H. M. Hobart, Chairman, General Electric Co., Schenectady, N. Y.

C. A. Adams,	W. J. Foster,	P. M. Lincoln,
P. L. Alger,	G. H. Garcelon,	A. M. MacCutcheon,
B. F. Bailey,	C. M. Gilt	V. M. Montsinger,
B. L. Barns,	Harold Goodwin	F. D. Newbury,
B. A. Behrend,	R. A. Hentz,	L. C. Nichols,
A. C. Bunker,	C. F. Hirshfeld,	E. B. Paxton,
James Burke,	B. G. Jamieson,	N. L. Pollard,
W. M. Dann,	J. A. Johnson,	R. F. Schuchardt,
L. L. Elden,	V. Karapetoff,	A. Still,
G. Faccioli,	A. H. Kehoe,	E. C. Stone
C. J. Fechheimer,		R. B. Williamson.

ELECTROCHEMISTRY AND ELECTROMETALLURGY

G. W. Vinal, Chairman, Bureau of Standards, Washington, D. C.

Lawrence Addicks,	Safford K. Colby,	Magnus Unger,
A. N. Anderson,	F. A. J. Fitzgerald,	J. B. Whitehead,
T. C. Atchison,	Walter E. Holland,	J. L. Woodbridge,
Farley G. Clark,	F. A. Lidbury,	J. L. McK. Yardley.
	C. G. Schluederberg,	

ELECTROPHYSICS

V. Karapetoff, Chairman, Cornell University, Ithaca, N. Y.

Oliver E. Buckley,	W. B. Kouwenhoven,	J. H. Morecroft,
V. Bush,	M. E. Leeds,	Chester W. Rice,
J. F. H. Douglas,	K. B. McEachron,	J. Slepian,
Charles Fortescue,	R. A. Millikan,	Harold B. Smith,
Carl Kinsley		J. B. Whitehead.

INSTRUMENTS AND MEASUREMENTS

A. E. Knowlton, Chairman, Dunham Laboratory, Yale University, New Haven, Conn.
E. D. Doyle, Vice-Chairman, New York, N. Y.

O. J. Bliss,	W. M. Goodwin, Jr.,	L. T. Robinson,
Perry A. Borden,	W. B. Kouwenhoven,	E. J. Rutan,
W. M. Bradshaw,	P. M. Lincoln,	B. W. St. Clair,
H. B. Brooks,	W. M. McConahey,	G. A. Sawin,
J. R. Craighead,	Wm. J. Mowbray,	I. B. Smith,
W. A. Del Mar,	H. A. Perkins,	H. M. Turner,
Melville Eastham,	R. T. Pierce,	Roy Wilkins.

APPLICATIONS TO IRON AND STEEL PRODUCTION

A. G. Pierce, Chairman, 1239 Guardian Building, Cleveland, Ohio

A. C. Bunker,	S. L. Henderson,	J. W. Speer,
A. C. Cummins,	R. H. Keil,	G. E. Stoltz,
F. B. Crosby,	W. C. Kennedy,	T. S. Towle,
J. H. Hall,	A. G. Place,	J. D. Wright.
	F. O. Schnure,	

PRODUCTION AND APPLICATION OF LIGHT

P. S. Millar, Chairman, Electrical Testing Laboratories, 80th St. & East End Ave., New York

W. T. Blackwell,	G. C. Hall,	F. H. Murphy,
J. M. Bryant,	L. A. Hawkins,	F. A. Rogers,
J. R. Cravath,	H. H. Higbie,	B. E. Shackelford,
W. T. Dempsey,	C. L. Kinsloe,	C. J. Stahl,
William Esty,	A. S. McAllister,	G. H. Stickney.
	George S. Merrill,	

APPLICATIONS TO MARINE WORK

G. A. Pierce, Chairman, Wm Cramp & Sons S. & E. B. Co., Philadelphia, Pa.
R. A. Beekman, Vice-Chairman, Schenectady, N. Y.

Commdr. C. S. Gillette,	A. Kennedy, Jr.,	H. M. Southgate,
H. F. Harvey, Jr.,	Commdr. M. A. Libbey,	W. E. Thau,
Wm. Hetherington, Jr.,	E. B. Merriam,	C. P. Turner,
H. L. Hibbard,	I. H. Osborne,	A. E. Waller,
Edward C. Jones,	William H. Reed,	J. L. Wilson,
J. S. Jones,		R. L. Witham.

APPLICATIONS TO MINING WORK

W. H. Lesser, Chairman, Madeira Hill & Co., Frackville, Pa.

M. C. Benedict,	Carl Lee,	W. F. Schwedes,
F. N. Bosson,	John A. Malady,	E. D. Stewart,
Graham Bright,	Charles H. Matthews,	F. L. Stone,
L. C. Ilsley,	F. C. Nicholson,	W. A. Thomas,
G. M. Kennedy,	H. F. Pigg,	E. B. Wagner,
R. L. Kingsland,	L. L. Quigley,	J. F. Wiggert,
A. B. Kiser,	Herbert S. Sands,	C. D. Woodward.

GENERAL POWER APPLICATIONS

A. M. MacCutcheon, Chairman, Reliance Electric & Engineering Co., 1088 Ivanhoe Road, Cleveland, Ohio

A. E. Arnold,	R. A. Hentz	H. W. Price,
D. H. Braymer,	H. D. James,	H. L. Smith,
R. C. Deale,	P. C. Jones,	A. H. Stebbins,
C. W. Drake,	A. C. Lanier,	E. C. Stone,
Clyde D. Gray,	W. S. Maddocks,	W. H. Timbie,
C. Francis Harding,	N. L. Mortensen,	F. M. Weller,
E. W. Henderson,	K. A. Pauly,	W. C. Yates.
	D. M. Petty,	

POWER GENERATION

H. W. Eales, Chairman, 315 N. 12th Boulevard, St. Louis, Mo.
J. T. Lawson, Vice-Chairman, Newark, N. J.

Vern E. Alden,	H. A. Kidder,	M. M. Samuels,
H. A. Barre,	W. H. Lawrence,	F. A. Scheffler,
E. T. Brandon,	F. T. Leilich,	R. F. Schuchardt,
N. E. Funk,	James Lyman,	Arthur R. Smith,
W. S. Gorsuch,	W. E. Mitchell,	Nicholas Stahl,
C. F. Hirshfeld,	I. E. Moultrop,	B. Tikhonovitch,
Francis Hodgkinson,		W. M. White.

POWER TRANSMISSION AND DISTRIBUTION

Philip Torchio, Chairman, 124 E. 15th St., New York, N. Y.
R. H. Tapscott, Vice-Chairman, New York, N. Y.

R. W. Atkinson,	Herbert H. Dewey,	W. E. Mitchell,
A. O. Austin,	L. L. Elden,	C. R. Oliver,
F. G. Baum,	R. D. Evans,	F. W. Peek, Jr.,
R. D. Booth,	F. M. Farmer,	D. W. Roper,
J. A. Brundige,	C. L. Fortescue,	C. E. Schwenger,
V. Bush,	C. D. Gray,	A. E. Silver,
P. H. Chase,	J. P. Jollyman,	M. L. Sindeband,
George F. Chellis,	A. H. Kehoe,	H. C. Sutton,
Wallace S. Clark,	C. H. Kraft,	Percy H. Thomas,
Edith Clarke,	A. H. Lawton,	Theodore Varney,
R. N. Conwell,	E. A. Loew,	H. S. Warren,
John C. Damon,	W. E. Meyer,	R. J. C. Wood,
W. A. Del Mar,		H. R. Woodrow.

PROTECTIVE DEVICES

F. L. Hunt, Chairman, Turners Falls Power & Electric Co., Greenfield, Mass.
H. R. Summerhayes, Vice-Chairman, Schenectady, N. Y.

W. S. Edsall,	H. C. Louis,	J. M. Oliver,
H. Halperin,	W. B. Kirke,	E. J. Rutan,
F. C. Hanker,	K. B. McEachron,	H. P. Sleeper,
E. A. Hester,	W. H. Millan,	E. C. Stone,
J. Allen Johnson,	L. J. Moore,	A. H. Sweetnam,
M. G. Lloyd,		A. Royal Wood.

RESEARCH

John B. Whitehead, Chairman, Johns Hopkins University, Baltimore, Md.
F. W. Peek, Jr., Vice-Chairman, Pittsfield, Mass.

Edward Bennett,	B. Gherardi,	E. W. Rice, Jr.,
V. Bush,	V. Karapetoff,	D. W. Roper,
E. H. Colpitts,	A. E. Kennelly,	Clayton H. Sharp,
E. E. F. Creighton,	M. G. Lloyd,	C. E. Skinner,
W. F. Davidson,	C. E. Magnusson,	Harold B. Smith,
W. A. Del Mar,	Harold Pender,	R. W. Sorensen.

TRANSPORTATION

Cary T. Hutchinson, Chairman, 52 William St., New York, N. Y.

J. V. B. Duer,	H. A. Kidder,	W. B. Potter,
W. K. Howe,	John Murphy,	N. W. Storer,
D. C. Jackson,	W. S. Murray,	Richard H. Wheeler.

A. I. E. E. Representatives

AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE COUNCIL

M. I. Pupin, John B. Taylor.

AMERICAN BUREAU OF WELDING

H. M. Hobart.

AMERICAN COMMITTEE ON ELECTROLYSIS

B. J. Arnold N. A. Carle, F. N. Waterman.

AMERICAN ENGINEERING COUNCIL ASSEMBLY

Comfort A. Adams,	H. M. Hobart,	M. I. Pupin,
C. G. Adsit,	F. L. Hutchinson,	*E. W. Rice, Jr.,
*A. W. Berresford,	*D. C. Jackson,	*Charles F. Scott,
H. W. Eales,	William McClellan,	*C. E. Skinner,
*John H. Finney,	L. F. Morehouse,	Calvert Townley,
M. M. Fowler,	*Farley Osgood,	

*Members of Administrative Board

AMERICAN ENGINEERING STANDARDS COMMITTEE

H. M. Hobart, H. S. Osborne, C. E. Skinner,
L. T. Robinson (Alternate)

AMERICAN MARINE STANDARDS COMMITTEE

R. A. Beekman.

AMERICAN YEAR BOOK, ADVISORY BOARD

Edward Caldwell

APPARATUS MAKERS AND USERS, COMMITTEE OF NATIONAL RESEARCH COUNCIL

C. E. Skinner

BOARD OF TRUSTEES, UNITED ENGINEERING SOCIETY

H. H. Barnes, Jr. Bancroft Gherardi, G. L. Knight

CHARLES A. COFFIN FELLOWSHIP AND RESEARCH FUND COMMITTEE

C. C. Chesney

ELIMINATION OF FATIGUE, COMMITTEE ON, SOCIETY OF INDUSTRIAL ENGINEERS

C. Francis Harding

ENGINEERING FOUNDATION BOARD

Gano Dunn, L. B. Stillwell.

JOHN FRITZ MEDAL BOARD OF AWARD

Gano Dunn, Frank B. Jewett, M. I. Pupin
Farley Osgood.

JOINT COMMITTEE ON COMPENSATION

Charles F. Scott

JOINT COMMITTEE ON WELDED RAIL JOINTS

D. D. Ewing, A. P. Way.

JOINT CONFERENCE COMMITTEE OF FOUNDER SOCIETIES

The Presidents and Secretaries, *ex-officio*.

LIBRARY BOARD OF UNITED ENGINEERING SOCIETY

Edward D. Adams, F. L. Hutchinson, Alfred W. Kiddle,
E. B. Craft, W. I. Slichter.

NATIONAL FIRE PROTECTION ASSOCIATION, ELECTRICAL COMMITTEE

J. P. Jackson

NATIONAL FIRE WASTE COUNCIL

John H. Finney, J. P. Jackson.

NATIONAL MUSEUM OF ENGINEERING AND INDUSTRY BOARD OF TRUSTEES

Gano Dunn

NATIONAL RESEARCH COUNCIL, ENGINEERING DIVISION

John B. Whitehead Cary T. Hutchinson E. W. Rice, Jr
F. L. Hutchinson, *ex-officio*,

NATIONAL SAFETY COUNCIL, ELECTRICAL COMMITTEE OF A. S. S. E.—ENGINEERING SECTION

J. P. Jackson

THE NEWCOMEN SOCIETY

E. B. Craft

RADIO ADVISORY COMMITTEE, BUREAU OF STANDARDS

A. E. Kennelly

SOCIETY FOR THE PROMOTION OF ENGINEERING EDUCATION BOARD OF INVESTIGATION AND COORDINATION

Gano Dunn Frank B. Jewett.

U. S. NATIONAL COMMITTEE OF THE INTERNATIONAL ILLUMINATION COMMISSION

A. E. Kennelly, C. O. Mailloux, Clayton H. Sharp.

WASHINGTON AWARD, COMMISSION OF

L. A. Ferguson, Charles F. Scott.

U. S. NATIONAL COMMITTEE OF THE INTERNATIONAL ELECTROTECHNICAL COMMISSION

C. A. Adams,	H. A. Kidder, (*ex-officio*)	E. W. Rice, Jr.
C. C. Chesney, *ex-officio*,	John W. Lieb,	L. T. Robinson,
L. W. Chubb,	F. V. Magalhaes,	D. W. Roper,
W. A. Del Mar,	C. O. Mailloux,	Charles F. Scott,
Gano Dunn,	A. S. McAllister,	C. H. Sharp,
B. Gherardi,	William McClellan,	C. E. Skinner,
H. M. Hobart,	J. F. Meyer, *ex-officio*	N. W. Storer,
D. C. Jackson,	A. H. Moore,	John B. Taylor
F. B. Jewett,	F. D. Newbury,	Elihu Thomson.
A. E. Kennelly,	H. S. Osborne,	R. B. Williamson.
	Farley Osgood,	

LIST OF SECTIONS

Name	Chairman	Secretary
Akron	A. R. Holden	H. L. Steinbach, Electrical Engineering Dept., Goodyear Tire & Rubber Co., Akron, Ohio
Atlanta	C. E. Bennett	W. F. Oliver, Box 2211, Atlanta, Ga.
Baltimore	W.B. Kouwenhoven	R. T. Greer, Madison St. Building, Baltimore, Md.
Boston	Hartley Rowe	W. H. Colburn, 39 Boylston St., Boston, Mass.
Chicago	K. A. Auty	William Wurth, 1634 Peoples Gas Bldg., Michigan Ave. at Adams St., Chicago, Ill.
Cincinnati	W. P. Beattie	L. J. Gregory, Union Gas & Electric Co., Cincinnati, Ohio
Cleveland	H. L. Grant	W. E. McFarland, 720 Illuminating Bldg., Cleveland, Ohio
Columbus	R. J. B. Feather	W. T. Schumaker, 25½ North High St., Columbus, Ohio
Connecticut	A. E. Knowlton	R. G. Warner, Yale University, 10 Hillhouse Ave., New Haven, Conn.
Denver	W. H. Edmunds	R. B. Bonney, Telephone Bldg., P. O. Box 960, Denver, Colo.
Detroit-Ann Arbor	Harold Cole	F. H. Riddle, Champion Porcelain Co., Detroit, Mich.
Erie	F. A. Tennant	L. H. Curtis, General Electric Co., Erie, Pa.
Fort Wayne	D. W. Merchant	C. F. Beyer, General Electric Co., Fort Wayne, Ind.
Indianapolis-Lafayette	H. M. Anthony	J. D. Bailey, 48 Monument Circle, Indianapolis, Ind.
Ithaca	R. F. Chamberlain	G. F. Bason, Electrical Engineering Dept., Cornell University, Ithaca, N. Y.
Kansas City	R. L. Baldwin	S. M. De Camp, 510 Dwight Bldg., Kansas City, Mo.
Lehigh Valley	W. E. Lloyd, Jr.	G. W. Brooks, Pennsylvania Power & Light Co., 8th & Hamilton Sts., Allentown, Pa.
Los Angeles	R. E. Cunningham	L. C. Williams, H. W. Hellman Bldg., Los Angeles, Calif.
Lynn	E. D. Dickinson	Chas. Skoglund, River Works, General Electric Co., W.Lynn, Mass.
Madison	E. J. Kallevang	H. J. Hunt, D. W. Mead & C. V. Seastone, State Journal Bldg., Madison, Wis.
Mexico	E. F. Lopez	H. Larralde, Isabel La Catolica, 33 Mexico, D. F., Mexico
Milwaukee	H.L.VanValkenberg	R. G. Lockett, Cutler-Hammer Mfg. Co., Milwaukee, Wis.
Minnesota	S. B. Hood	M. E. Todd, University of Minnesota, Minneapolis, Minn.
Nebraska	C. W. Minard	N. W. Kingsley, 1303 Telephone Bldg., Omaha, Nebr.
New York	E. B. Meyer	O. B. Blackwell, American Tel. & Tel. Co., 195 Broadway, New York, N. Y.
Niagara Frontier	H. B. Alverson	A. W. Underhill, Jr., 606 Lafayette Bldg., Buffalo, N. Y.
Oklahoma	E. R. Page	C. C. Stewart, Oklahoma Gas & Electric Co., Norman, Okla.
Panama	L. W. Parsons	I. F. McIlhenny, Box 413, Balboa Heights, C. Z.
Philadelphia	Louis J. Costa	R. H. Silbert, 2301 Market St., Philadelphia, Pa.
Pittsburgh	W. C. Goodwin	D. M. Simons, Standard Underground Cable Co., Cor. 17th & Pike Sts., Pittsburgh, Pa.
Pittsfield	E. F. Gehrkens	C. H. Kline, General Electric Co., Pittsfield, Mass.
Portland, Ore.	J. C. Henkle	J. E. Yates, Gasco Bldg., Portland, Ore.
Providence	Edwin E. Nelson	F. W. Smith, Blackstone Valley Gas & Electric Co., Pawtucket, R. I.
Rochester	Earl C. Karker	Wade H. Reichard, General Ry. Signal Co., Rochester, N. Y.
St. Louis	W. H. Millan	L. N. Van Hook, 3869 Park Ave., St. Louis, Mo.
San Francisco	R. C. Powell	A. G. Jones, 807 Rialto Bldg., San Francisco, Calif.
Saskatchewan	S. R. Parker	W. P. Brattle, Dept of Telephones, Telephone Bldg., Regina, Sask.
Schenectady	R. E. Doherty	R. F. Franklin, Room 301, Bldg. No. 41, General Electric Co., Schenectady, N. Y.
Seattle	C. E. Mong	C. R. Wallis, 609 Colman Bldg., P. O. Box 1858, Seattle, Wash.
Sharon	H. L. Cole	L. E. Hill, Westinghouse Elec. & Mfg. Co., Sharon, Pa.

LIST OF SECTIONS—*Continued*

Name	Chairman	Secretary
Southern Virginia	W. S. Rodman	J. H. Berry, 1338 Rockbridge Ave., Norfolk, Va.
Spokane	Richard McKay	James B. Fisken, Washington Water Power Co., Lincoln & Trent, Spokane, Wash.
Springfield, Mass.	L. F. Curtis	J. Frank Murray, United Electric Light Co., 251 Wilbraham Ave., Springfield, Mass.
Syracuse	C. E. Dorr	F. E. Verdin, 615 City Bank Bldg., Syracuse, N. Y.
Toledo	A. H. Stebbins	Max Neuber, 1257 Fernwood Ave., Toledo, Ohio
Toronto	M. B. Hastings	F. F. Ambuhl, Toronto Hydro-Electric System, 226 Yonge St., Toronto, Ontario
Urbana	J. T. Tykociner	L. B. Archer, 308 Electrical Engineering Lab., University of Illinois, Urbana, Ill.
Utah	B. C. J. Wheatlake	D. L. Brundige, Utah Power & Light Co., Box 1790, Salt Lake City, Utah
Vancouver	R. L. Hall	C. W. Colvin, B. C. Electric Railway Co., 425 Carrall St., Vancouver, B. C.
Washington, D. C.	C. A. Robinson	D. S. Wegg, Elec. Equipment Div. Bureau of Foreign & Domestic Commerce, Washington, D. C.
Worcester	C. F. Hood	F. B. Crosby, Morgan Construction Co., 15 Belmont St., Worcester, Mass.
Total 51		

LIST OF BRANCHES

Name and Location	Chairman	Secretary	Counselor (Member of Faculty)
Alabama Polytechnic Institute, Auburn, Ala	J. D. Stewart	I. L. Knox	W. W. Hill
Alabama, University of, University, Ala	C.E. Rankin	Sewell St. John	
Arizona, University of, Tucson, Ariz	J. W. Cruse		Paul Cloke
Arkansas, University of, Fayetteville, Ark	Carroll Walsh	W. H. Mann	W. B. Stelzner
Armour Institute of Technology, Chicago, Ill	M. T. Goetz	C. W. Schramm	D. P. Moreton
Brooklyn Polytechnic Institute, Brooklyn, N. Y	F. Wanpel	Joseph Heller	Robin Beach
Bucknell University, Lewisburg, Pa	A. Fogelsanger	J. D. Johnson	W. K. Rhodes
California Institute of Technology, Pasadena, Calif	Thomas Gottier	Alan Capon	R. W. Sorensen
California, University of, Berkeley, Calif	C. F. Dalziel	R. S. Briggs	T. C. McFarland
Carnegie Institute of Technology, Pittsburgh, Pa	J. R. Power	R. O. Perrine	B. C. Dennison
Case School of Applied Science, Cleveland, O	C. A. Baldwin	A. B. Anderson	H. B. Dates
Catholic University of America, Washington, D. C	B. J. Kroeger	J. E. O'Brien	T. J. MacKavanaugh
Cincinnati, University of, Cincinnati, O	F. Sanford	W. C. Osterbrock	W. C. Osterbrock
Clarkson College of Technology, Potsdam, N. Y	W. R. MacGregor	L. G. Carney	A. R. Powers
Clemson Agricultural College, Clemson College, S. C	B. V. Martin	W. H. Sudlow	S. R. Rhodes
Colorado State Agricultural College, Ft. Collins, Colo	C. O. Nelson	D. W. Asay	
Colorado, University of, Boulder, Colo	A. D. Thomas	J. A. Setter	W. C. DuVall
Cooper Union, New York, N. Y	F. H. Miller	H. T. Wilhelm	Norman L. Towle
Denver, University of, Denver, Colo	Harold Henson	Allea Ohlson	R. E. Nyswander
Drexel Institute, Philadelphia, Pa	H. D. Baker	R. S. Eininger, Jr.	E. O. Lange
Florida, University of, Gainesville, Fla	O. B. Turbyfill	R. Theo. Lundy	J. M. Weil
Georgia School of Technology, Atlanta, Ga	W. M. McGraw	F. L. Kaestle	E. S. Hannaford
Idaho, University of, Moscow, Idaho	J. W. Gartin	S. Blore	J. H. Johnson
Iowa State College, Ames, Iowa	P. E. Benner	H. J. Biddulph	F. A. Fish
Iowa, University of, Iowa City, Iowa	L. Dimond	A. C. Boeke	A. H. Ford
Kansas State College, Manhattan, Kans	A. M. Young	John Yost	C. E. Reid
Kansas, University of, Lawrence, Kans	W. L. Immer	H. R. Hilkey	G. C. Shaad
Kentucky, University of, Lexington, Ky	J. A. Weingartner	C. E. Albert	
Lafayette College, Easton, Pa	A. H. Gabert	F. G. Keim	Morland King
Lehigh University, S. Bethlehem, Pa	F. G. Kear	J. H. Shuhart	J. L. Beaver
Lewis Institute, Chicago, Ill	O. D. Westerberg	R. G. Raymond	F. A. Rogers
Maine, University of, Orono, Me	S. B. Coleman	H. S. McPhee	W. E. Barrows, Jr.
Marquette University, Milwaukee, Wis	C. H. Legler	M. J. Smith	J. F. H. Douglas

DIGEST OF CURRENT INDUSTRIAL NEWS

NEW CATALOGUES AND OTHER PUBLICATIONS

Mailed to interested readers by issuing companies

Transformers.—Bulletin GEA-424, 72 pp. Describes G-E distribution and small power transformers. General Electric Company, Schenectady, N. Y.

Radio Frequency Ammeters.—Bulletin 810, 4 pp. Describes the Roller-Smith thermal ammeters and milli-ammeters for measuring radio frequency currents. Roller-Smith Company, 12 Park Place, New York.

Automatic Stations.—Bulletin GEA-90A, 48 pp. Describes G-E automatic stations. Numerous installations in various industries are pictured in the book. General Electric Co., Schenectady, N. Y.

Jagabi Rheostats.—Catalog 1140, 20 pp. Describes a line of adjustable resistances suitable for practically every need in electrical, physical, chemical, research and educational laboratories. A number of improvements have recently been made in these devices. James G. Biddle, 1211 Arch Street, Philadelphia, Pa.

Watthour Meters.—Bulletin C1753, 16 pp., "Registers of Revenue," is a Westinghouse publication dealing with the advantages of the watthour meter. The permanent accuracy of the meter, low costs of adjustments, tests and handling, ease in reading and saving of storage space are some of the points covered. Westinghouse Electric & Mfg. Company, East Pittsburgh, Pa.

NOTES OF THE INDUSTRY

Edgar S. Bloom elected President of the Western Electric Company.—Election of Edgar S. Bloom, a vice-president of the American Telephone and Telegraph Company, to the presidency of the Western Electric Company, has been announced. He succeeds Charles G. DuBois, who has been president for the past seven years, and who continues with the company as Chairman of the Board of Directors.

Harry S. Schott appointed General Sales Manager of National Carbon Company, Inc.—The appointment on August 1 of Harry S. Schott as general sales manager of the National Carbon Company, Inc. has been announced. He has been associated with the company since 1913, and has been identified with the manufacturing and jobbing end of the electrical industry for almost twenty-five years.

The Kuhlman Electric Company, Bay City, Michigan, manufacturers of power, distribution and street lighting transformers, announces the appointment of H. F. Darby, Jr., 1700 Walnut Street, Philadelphia, Pa., as direct factory representative in the Philadelphia district. For more than twenty years Mr. Darby was with the Cutter Electrical & Manufacturing Company and during the last six years he was sales manager of that organization.

The Jas. R. Kearney Corporation is Organized.—James R. Kearney, for the past fifteen years associated with the W. N. Matthews Corporation, is president of the new Jas. R. Kearney Corporation, manufacturers of utility equipment, located at 4224-32 Clayton Avenue, St. Louis, Mo. Mr. Kearney has had wide experience in specialty equipment manufacturing, plant engineering and pole line and underground construction. A number of well known specialties are manufactured under his patents. A group of engineers and well known figures in the electrical industry are associated with Mr. Kearney in his new enterprise.

Great Increase in Exports of U. S. Products.—The Bureau of Foreign and Domestic Commerce reports that exports of finished manufactures show an increase during the fiscal year just ended, of 16 per cent over the previous year. They were 60 per cent greater than in 1921-1922 and nearly three times as great in value as in the five year period before the war. Even after allowing for higher prices, they were more than double the pre-war average. Dr. Julius Klein, Director of the Bureau, states that this large growth reflects the ever rising efficiency of American industry and the energy and intelligence of American salesmanship in foreign markets.

The export of electrical machinery and apparatus amounted to over $80,000,000 in the fiscal year 1925-1926, as compared to $67,000,000 in 1924-1925 and $57,000,000 for the year 1921-1922. The total value of the exports of semi-manufactures and finished manufactures amounted to $2,573,000,000 for the fiscal year 1925-1926, an increase of 50 per cent in five years.

Equipment for Conowingo.—Three vertical-shaft hydraulic turbines, each of 54,000 horse power, will be constructed by the William Cramp & Sons Ship & Engine Building Company, of Philadelphia, in carrying out the great power development of the Philadelphia Electric Company at Conowingo, on the Susquehanna River. Though they are exceeded by a few installations in power capacity, on account of the lower head requirements the physical dimensions of the new units will exceed those of any hydraulic turbine yet constructed. The head at Conowingo will be 89 feet and the turbines will operate at a speed of 81.8 revolutions per minute.

The General Electric Company will supply thirteen transformers for the Conowingo project. These are to be used in transmitting 350,000 horse power of electrical energy over seventy miles of transmission lines to Philadelphia. Each of the transformers, all of the water-cooled type, has a rated capacity of 26,667 kilovolt-amperes. The voltage will be stepped up from 13,800, at which the current will be generated, to 220,000, at which it will be transmitted. The transformers have an efficiency of better than 99 per cent.

Two Million Dollar Turbine Generator Contracts for Westinghouse.—Substantial increases in electric power production, both central station output as well as industrial power, are reflected in several contracts for power generating equipment just received by the Westinghouse Electric and Manufacturing Company. The contracts aggregate a total of 120,000 electric horse power, of which approximately 90,000 will be for additional power company current, and when completed will represent an outlay of approximately $2,000,000.

The biggest contract was placed by the Duquesne Light Company for one turbine generator of 60,000 horse power, one 62,500 square-foot steam condenser with auxiliaries and three transformers, each rated at 31,400 kv-a. The equipment is to be installed at the Colfax Station at Cheswick. This station at the present time has four generator units of approximately 250,000 horse power.

A contract placed by the Binghamton Light Heat & Power Company, Binghamton, New York, calls for delivery of one 45,000 horse power turbine generator as well as three transformers rated at 11,765 kv-a. each. The equipment is to be installed at the company's power station at Binghamton.

The third contract was received from the Solvay Process Company of Syracuse, New York, and includes two high pressure turbine generators of unusual design and of a total of approximately 15,000 horse power. While ordinarily big steam turbines operate at a steam pressure of from 200 to 400 pounds, these turbines will have a gage throttle pressure of seven hundred and twenty-five pounds. The installation is intended primarily to obtain steam economies and utilize by-product power.

All the steam power equipment will be built at the South Philadelphia Works, while the electrical equipment will be supplied by the East Pittsburgh shops.

Activities and Development of the Meetings and Papers Committee

Technical meetings of the Institute are held primarily for the purpose of bringing to the attention of the membership, current developments in the electrical art and of affording an opportunity for the interchange of views on electrical subjects. Responsibility for accomplishing these objectives rests with the Meetings and Papers Committee.

This committee is admirably fitted to keep in contact with electrical progress and to arrange for the presentation and discussion of papers. Its members include the chairmen of the sixteen technical committees and ten other members of the Institute.

The committee chairmen, through frequent meetings of their respective committees, and the remaining members through other contacts, keep in intimate touch with progress in all branches of electrical science.

The present policy with regard to conventions and the present organization of the Meetings and Papers Committee have evolved with the growth of the Institute and the accumulated experience of past years.

A system for handling papers and meetings became necessary at the very beginning of the Institute in 1884. At first these were handled by the Council, which corresponded to the present Board of Directors. In the first year one technical meeting was held and ten papers presented. In the same year the first predecessor of the present committee was appointed. It was called the Meetings and Exhibitions Committee and had three members. One technical meeting was held in 1885 and two in 1886. In the latter year it was decided to hold monthly meetings and a Committee on Monthly Meetings, consisting of three members, was appointed. The monthly meetings were started in 1887 and continued as Institute meetings until 1921.

As the Institute grew, it was found necessary in 1888 to appoint a Committee on Papers and Meetings, consisting of five members, and a separate Editing Committee, of three members. These two committees were combined in 1893, but were separated again in 1901.

The first two technical committees were appointed in 1906. In 1907 there were three technical committees and these were attached as subcommittees to the Meetings and Papers Committee, as it now was called.

In 1909 the technical committees, of which there were then six, were separated from the Meetings and Papers Committee, but in order to retain contact, their chairmen were made members of this committee. This plan is still in effect today, though the number of technical committees has increased to sixteen.

Institute meetings were held monthly, except during the summer, from 1887 until 1921. At first these were held in New York, but in later years many were held in other cities. In 1921 it was decided that there should be only three national Institute conventions and that monthly meetings should be classed as Section meetings. At that time there were forty-two Sections holding regular Section meetings.

The three national conventions were to be the Annual Convention, started in 1884; the Pacific Coast Convention, started in 1910; and the Midwinter Convention, started as such in 1913. Another national meeting, known as a Spring Convention, was initiated in 1922, but it was discontinued after 1925, principally because of the development in regional meetings.

The present yearly program of the Institute includes three national conventions and a number of regional meetings. The number of regional meetings is not fixed but depends largely on the needs and desires of the various geographical districts. Three regional meetings were held in the year 1925-1926 but it is expected that in future the number of such meetings will increase.

It is of prime importance that the programs for conventions and meetings shall treat electrical subjects from a broad viewpoint and present technical information of interest to a large institute membership which includes all branches of the profession. With a membership composed of specialists, consulting engineers, operators, executives and others it is necessary to weigh all factors if a well balanced program is to be developed.

Furthermore, the Meetings and Papers Committee, in addition to the preparation of technical programs, develops its convention programs with a view to cooperating with public officials, financiers, executives and industrial leaders, in order to advance the status of the profession.

When a convention is being planned, this committee is guided very largely by the advice and wishes of the local convention committee, which has jurisdiction over all arrangements excepting the actual selection of technical papers. The local committee has an intimate knowledge of local conditions and can best suggest those elements which will give greatest benefit to the membership in its general territory. In this regard the

ocal convention and regional-meeting committees have been most helpful and have given most valuable co-operation.

Technical papers are submitted by the authors without solicitation on the part of the committee or in case it appears desirable to present information on some specific branch of the art, are obtained as the result of solicitation or suggestion by one or more of the committee members.

Upon receipt of a paper submitted for presentation or publication, the usual course is to refer it to the technical committee or committees conversant with the subject, for the purpose of securing an opinion as to its worth.

As a result of these and other opinions a paper is either accepted, rejected or returned to the author with constructive suggestions for its revision.

Discussion of papers is almost as important as their presentation and consequently the Meetings and Papers Committee endeavors to secure intelligent discussion at all meetings by general invitation and individual request.

E. B. MEYER,
Chairman, M. and P. Committee.

Some Leaders of the A. I. E. E.

Calvert Townley, the thirty-second president of the Institute, 1919-1920, was born in Cincinnati, Ohio, Oct. 18, 1864. He prepared for college at Chickering Institute, that city, and was graduated from the Sheffield Scientific School of Yale in 1886. Returning there for a graduate course he received the degree of M. E. in 1888. A summer as a laborer helping to rebuild the burned station of the Brush Electric Light Co. of Cincinnati was followed by a seventeen year engagement with the Westinghouse Electric interests at Pittsburgh, Cincinnati, Boston and New York. Starting as road engineer, or trouble man, and later becoming designer of distribution systems he was shortly transferred to the sales department. Here, although officially free from engineering duties, his inclination led him to study the technical problems, first of electric light then of power and finally of traction. He was active in the Niagara Falls development, the equipment of the Boston subways, the New York and Brooklyn elevated systems and the New York subway. In 1904, he went with the N. Y. N. H. & H. R. R. as acting fourth vice-president, to electrify their line out of New York. About that time this railroad began acquiring utility companies, (largely trolley lines) and Mr. Townley was appointed first vice-president of the holding company to manage their utilities as a side issue. The "side issue" soon reached such magnitude that after completing electrification plans and drawing specifications, Mr. Townley asked to be relieved of construction duties and became consulting engineer for the New Haven Railroad thereafter devoting most of his time to executive management of the utilities. In 1911 he renewed his former connection with the Westinghouse Company as assistant to the president a position which he now holds. During the latter period, he has served as president of the Lackawanna & Wyoming Valley Railroad, vice-president of the Niagara, Lockport & Ontario Power Co., vice-president of the South Philadelphia Co., vice-president of the International Radio Telegraph Company and officer or director of many other companies. He has toured Europe and South America in professional capacity. During the war he superintended the erection of a turbine factory near Philadelphia, the output being very largely used for the Federal Government merchant and naval vessels.

Mr. Townley joined the A. I. E. E. as an associate in 1901 and became a Fellow in 1912. He was elected Manager in 1905, vice-president in 1908 and President in 1919. In 1923 he was chairman of the New York Section; for over five years he was chairman of the Public Policy Committee, for two chairman of the Finance Committee and, at various times, served on other Committees, including Executive, Meetings and Papers, Standards, Edison Medal and Constitution Revision. He served as vice-president and trustee of The United Engineering Society and on The Engineering Foundation Board. In 1919, Mr. Townley was chairman of the Special Committee on Development which studied the needs of the Institute and of the profession. Out of this study came the joint committee of the four Founder Societies on which he served, and then on The Engineering Council. Mr. Townley was chairman of the Organizing Conference of American Engineering Council at Washington, was elected a vice-president, later declining the presidency. He was a delegate and member of the Executive Committee of the American delegation to the World Power Conference in London in 1924 and a member of the American Industrial Mission to Mexico that same year. He has contributed many papers, mostly dealing with power and traction problems.

It is estimated that between 12,000,000 and 15,000,000 radio sets are in operation throughout the world, according to a survey recently made. Of these, the United States is believed to have nearly half, or more than 5,500,000 sets.

About 900 broadcasting stations are now operating, more than 500 being in the United States. The actual number of stations which may be operating is, of course, considerably less, owing to the number of divided-time agreements in force; this practise, however, is not common in foreign countries, as the stations are fewer and the distances between them greater. The wave bands used abroad are also much wider.

Carrier-Current Communication on Submarine Cables

Los Angeles-Catalina Island Telephone Circuits

BY H. W. HITCHCOCK[1]

Associate, A. I. E. E.

Synopsis.—*Seven telephone channels and one telegraph channel on one single-conductor deep-sea cable have been made possible by the employment of carrier current on one of the two submarine cables across Catalina channel. This is the only application of carrier telephony to deep-sea cables; the system is the shortest carrier system (26 mi.) in commercial operation; it provides more separate carrier channels (six) than has been previously attempted; and it differs in other important respects from other systems. This paper describes this carrier-current system.*

* * * * *

IN the commercial application of new developments in the electrical communication art, there are a few places which repeatedly call attention to themselves. Notable among these is Catalina Island, for it is probable that in providing telephone service across the short expanse of water which separates Catalina from the mainland, more novel improvements have been employed than at almost any other point.

The first commercial telephone communication with Catalina Island was established in 1920 when a radio system was placed in operation between Avalon and the mainland, the circuit being extended by wire to Los Angeles. This circuit was in use for several years and featured in a number of transcontinental demonstrations, including the one which was held at the opening of the service to Havana over the Key West-Havana cables.

The system is of considerable interest as it represents the only instance in which radio has been used, in this country at least, to form a portion of a toll telephone system for the general use of the public. That it was reasonably successful is demonstrated by the fact that on some days as many as 183 commercial telephone messages and a large number of telegrams were handled over it. The system also proved to be one of the first popular broadcasting stations and many letters were received from radio fans, often several hundred miles away, telling of some of the amusing conversations which were overheard.

In 1923 the radio was replaced by two single-conductor submarine cables. By that time the demands for service were too great to be met by a single circuit, while the growing interest in radio broadcasting, as well as the increasing interference from ship transmitters, rendered its continued operation very difficult and unsatisfactory. The submarine cables were of the single-conductor, deep-sea type, each providing a single-wire circuit. They are of interest for a number of reasons, chiefly, perhaps, because they represent one of the few instances of deep-sea cable manufacture in this country. From the cable hut at San Pedro, the circuit is extended to the office by means of a special lead-covered cable containing four individually shielded No. 13 B & S gage pairs for the telephone circuits and four 19-gage pairs for the telegraph circuits and other miscellaneous uses. Between the San Pedro office and Los Angeles, the circuit was composed of a No. 19 B & S gage cable phantom. At San Pedro a through-line repeater was inserted in order to secure the desired over-all equivalent between Avalon and Los Angeles. A description of these cables and their laying was given in a paper presented by the writer at the Pacific Coast Convention in 1923 and published in Volume XLII of the TRANSACTIONS.

Although the two circuits provided by the cables represented a great improvement over the previous condition as regards the quality of the service rendered and the number of messages which could be handled, it was realized that they would soon prove inadequate to handle the heavy summer business, for which eight or ten circuits would be required in a relatively short time. To provide for such a large increase by the laying of additional cables was deemed impractical, as the cost would be excessive. Furthermore, in water of this depth—3000 ft. (914 meters)—it is important that cables be laid at least a mile or two apart, so that in the event that trouble develops on one, it can be repaired without disturbing any of the others. For a total distance as short as the width of the Catalina channel—23 nautical mi. (6087 ft. or 1856 meters per nautical mi.)—such a separation between adjacent cables could not be maintained without materially increasing the length of the outer ones with a corresponding increase in their cost and in their transmission equivalents. In view of these facts, it was decided to secure as many more circuits as possible by operating carrier systems over the two cables already in use. This project was actively promoted with the result that on May 15, 1926, six carrier telephone circuits were placed in operation.

The use of carrier in the past few years has increased so rapidly that the mere addition of a new system is,

1. Transmission and Protection Engineer, Southern California Tel. and Tel. Co., Los Angeles, Calif.

Presented at the Pacific Coast Convention of the A. I. E. E., Salt Lake City, Utah, Sept. 6-9, 1926.

in itself, of hardly more than passing interest. In this instance, however, there are a number of factors which render the project of particular interest. It is the shortest carrier system—26 mi. (43 km.)—in commercial operation. It is the only application of carrier telephone to deep-sea cables; the system provides more separate channels (six) than has ever before been attempted, while the particular arrangement employed is different in many other important respects from anything which has been used in the past.

In order to better appreciate the reasons for adopting the system finally agreed upon, it may be of interest to review briefly the essential characteristics of carrier systems and the different types which are available. The general principles of carrier-current telephony are described at considerable length in a paper by Messrs. Colpitts and Blackwell which was published in Volume XL of the JOURNAL of the Institute.

Carrier systems may be divided into two general classes, namely, balanced or grouped, depending upon

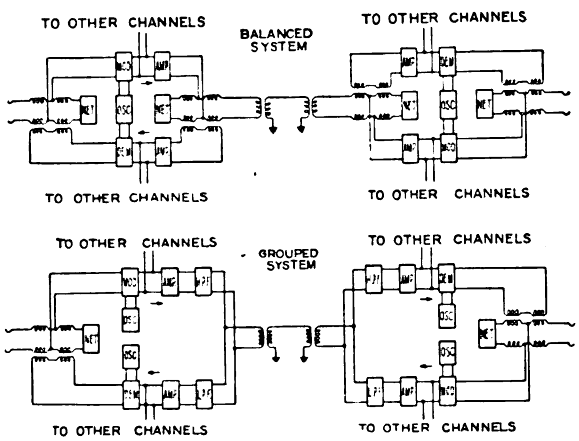

FIG. 1

the manner in which the currents in the two directions are prevented from interfering with each other at the terminals. In the balanced system this separation is accomplished by means of a three-winding transformer or hybrid coil together with a balancing artificial line such as is used with a voice-frequency repeater. In the grouped system, different carrier frequencies are used for transmission in the two directions and their separation at the terminals is effected by means of suitable band-pass filters. These two systems are shown diagrammatically in Fig. 1. The balanced system has the advantage that for each channel the same carrier frequency may be used for transmission in both directions so that there may be as many channels as there are separate carrier frequencies. On the other hand, the wire circuit must be very uniform throughout so that the impedance will be very regular over the entire carrier-frequency range, and may be simulated by an artificial line. The line must also be very stable so that the impedance balance, once having been secured, will not be disturbed. Furthermore, as transmission with the same carrier takes place in the two directions, the effect of the cross-talk between systems of the same type is very severe, so that it is usually impractical to operate two of these over wires which are in close proximity for any considerable distance. The grouped system has the advantage that a balancing line is not required and hence small circuit irregularities are relatively unimportant. Furthermore, the effect of

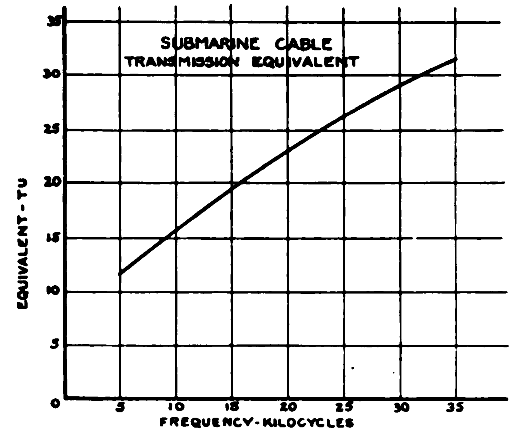

FIG. 2

cross-talk is much less severe, so that a number of systems may often be operated over adjacent circuits. One disadvantage is that two carrier frequencies are required for each channel so that fewer circuits can be secured with one system.

Carrier systems may also be divided into two classes depending upon the manner in which the carrier current is provided at the receiving end. In the carrier transmission system, the carrier current is supplied by the oscillator at the sending end and is transmitted over the circuit along with one or both of the side bands. In the carrier suppression system, the carrier current itself is not transmitted but is introduced into the receiving equipment from a local source. This latter system is proving to be superior for general carrier purposes because of the advantages which accrue from relieving

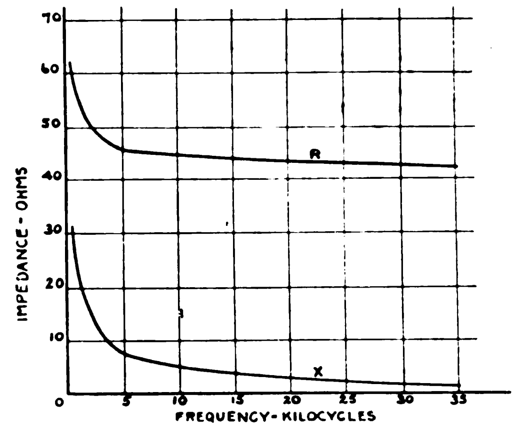

FIG. 3

the line and apparatus from the load of the carrier current.

Turning now to the electrical characteristics of the cables, we find that each one provides a circuit having a transmission equivalent which increases throughout the carrier range but is moderate in magnitude. The impedance, as is to be expected with a uniform, non-loaded cable, is very smooth, and since there is no opportunity for any change in the cable constants, the impedance has practically no variation. The transmission equivalent and the impedance of one of the cables are shown in Figs. 2 and 3 respectively. The cross-talk between the cables is small enough to be entirely negligible, regardless of the type of carrier systems employed.

In view of all the conditions outlined, a balanced system of the carrier suppression type was decided upon. Such a system provides the maximum number of channels per cable, while the usual difficulties of impedance balance and inter-system cross-talk are largely absent due to the unusual characteristics of the cables. The adoption of such a system also made possible the employment of standard units of equipment of the most recent design. The general nature of the system and the arrangement of the component parts is shown diagrammatically in Fig. 4. Fig. 5 is a simplified circuit diagram showing the filters for separating the various circuits at the terminals, together with the balancing arrangement. In Fig. 6 are shown the essential parts of one channel together with the amplifiers

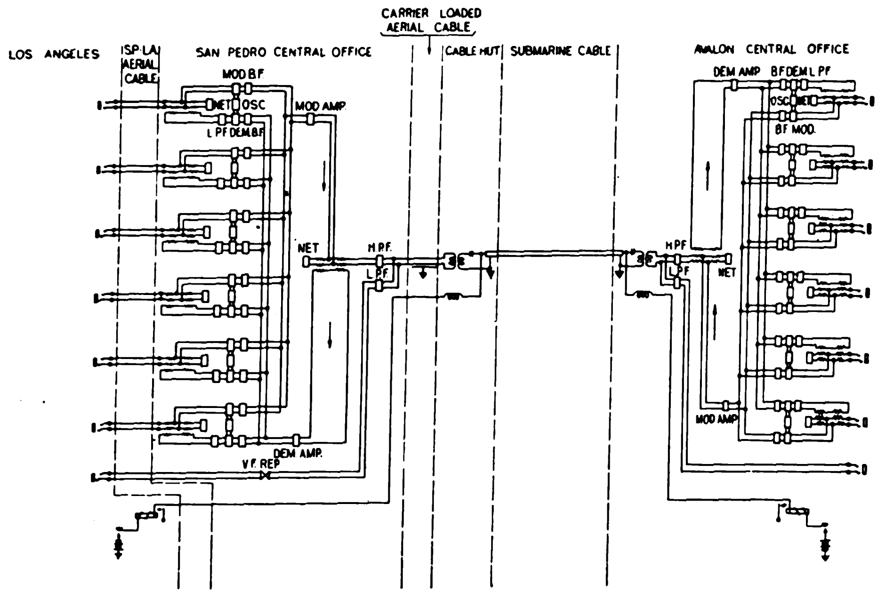

Fig. 4

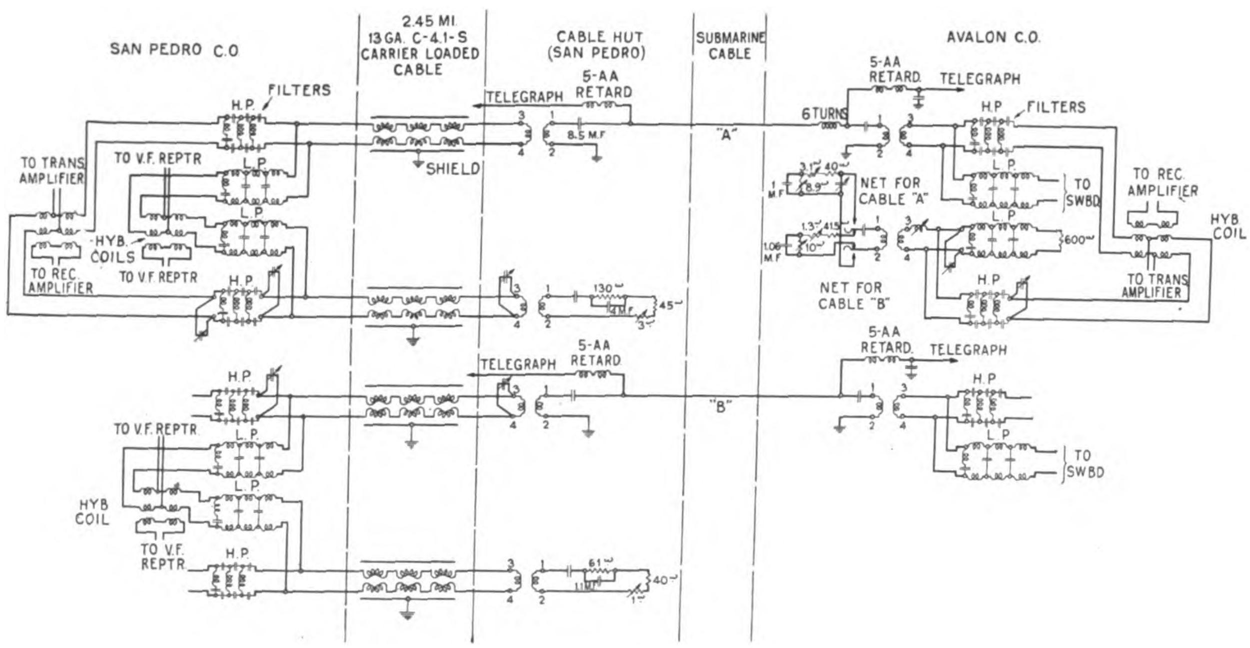

Fig. 5

and the hybrid coil which are common to all the channels. For convenience, some of the battery and auxiliary circuits have been omitted in the figure.

At the time the system was under development, it was uncertain that balanced operation of all channels over a single cable would be practicable, so that an alternative arrangement involving substantial four-wire operation over the two cables was provided for. With this arrangement, which is shown diagrammatically in Fig. 7, all transmission in one direction takes place over one cable, while transmission in the opposite direction is effected over the second cable. No balancing equipment or hybrid coils are employed. Such an arrangement would increase the system stability, if such were required, but would limit the total carrier capacity of the two cables to six channels. In the event of the failure of one cable, operation with such a system would be impossible, and it would be necessary, at that time, to revert to the two-wire arrangement as described above, with a possible reduction in the over-all gain or a reduction in the number of operating channels.

As may be seen from Fig. 4, a carrier-equipped cable provides a d-c. telegraph circuit, and one voice-frequency, and six carrier-frequency telephone channels. The separation of the various channels is effected by means of electrical filters. Fig. 8 shows the band of frequencies employed for each channel. For the d-c. telegraph this separation is effected at the terminals of the cable as is shown in Fig. 5. The telegraph circuit requires a continuous d-c. path, whereas the telephone channels require the insertion of an inequality ratio

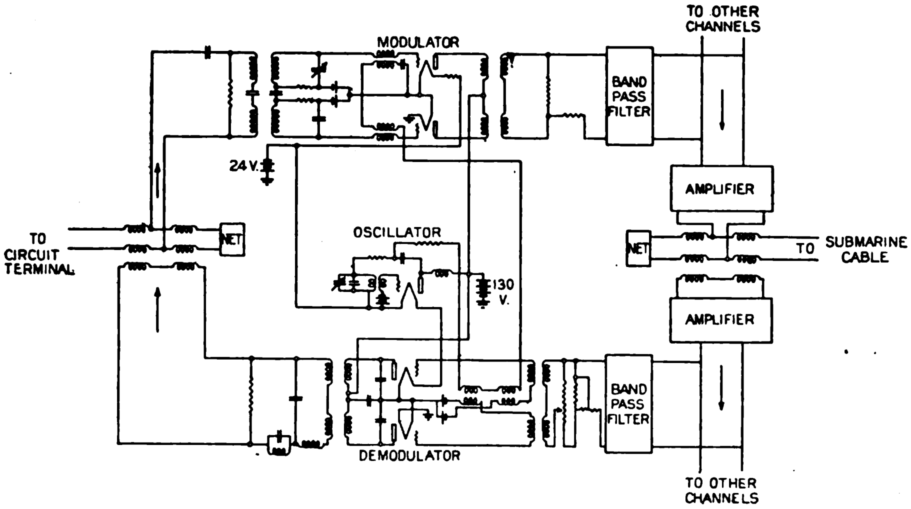

Fig. 6

insulating transformer at the ends of the cable in order to properly join the 43-ohm grounded cable circuit with the 600-ohm metallic circuit formed by the office equipment and intermediate cable. As this transformer must pass both the voice and carrier channels, it has been designed so as to have a high efficiency for all frequencies between 250 and 30,000 cycles. Separation of the voice-frequency circuit from the carrier system is performed by means of the usual high and low pass filters which are located at the central offices. These filters both have a cut-off frequency of 3000 cycles, the low pass transmitting all frequencies below this value and the high pass transmitting all above it. In the carrier system the transmitting and receiving currents are separated from each other by a hybrid

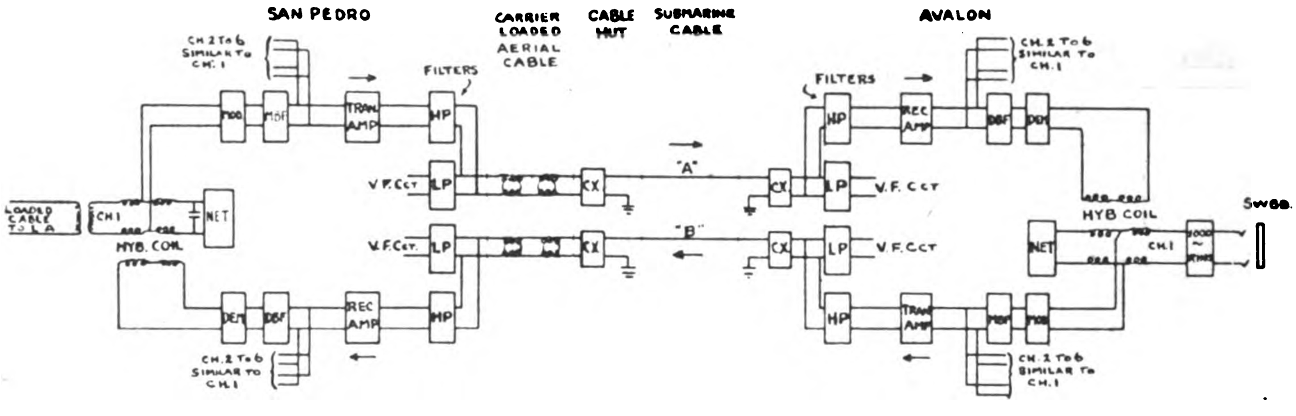

Fig. 7

coil and balancing network. Between the output of the six modulators and the common transmitting amplifier, individual band-pass filters are located. Each one of these filters is designed to transmit one of the side bands produced by the modulator associated with it and to suppress all other frequencies. The six receiving currents are separated in a similar manner. Each filter allows current of the proper frequency to pass to the corresponding demodulator and excludes all others. Each demodulator is also provided with a low

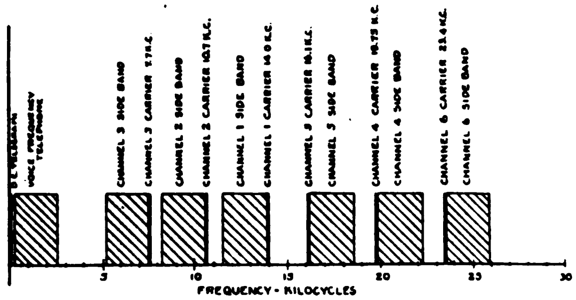

Fig. 8

pass filter which allows the passage of the resulting voice-frequency current but excludes all incidental higher frequencies which might be present and render the circuit noisy. The input of each modulator and the output of the corresponding demodulator are finally joined by means of a voice-frequency hybrid coil and extended to the circuit terminal as a two-wire circuit. At the San Pedro end, each two-wire circuit is extended to Los Angeles over a loaded cable circuit. Phantoms are employed for this purpose as they have a higher cut-off frequency than have the side circuits, with a correspondingly better quality.

Concerning the carrier system itself, the two ends are practically identical while the general equipment arrangement for an individual channel is the same in all cases except for the frequency of the band-pass filter. For this reason, a consideration of one channel is sufficient. Each channel is composed of a voice-frequency hybrid coil, a modulator with its band-pass filter, an oscillator, and a demodulator, together with its associated filters. In addition, there is, at each end, a carrier hybrid coil together with transmitting and receiving amplifiers which are common to all channels. The arrangement of this equipment is shown schematically in Fig. 6, as previously indicated.

The modulator the input of which is connected to the center taps of the hybrid coil line windings consists of two vacuum tubes arranged for push-pull operation. The carrier current which is supplied by the oscillator is applied to the two grids by means of a transformer. Such a circuit generates the two side bands but suppresses the carrier. In order that this suppression may be as complete as possible, the small condenser associated with the grid of one of the tubes is made variable and is adjusted until the carrier current in the modulator output is reduced to a minimum. The band-pass filter transmits one of the side bands and suppresses the other, as well as all miscellaneous resultant currents of a higher order which are produced by the modulator. It also prevents the output currents of the other channels from entering the modulator circuit as this would cause a reduction in their efficiency and give rise to undesirable frequencies.

The demodulator is very similar to the modulator. The tube arrangement is substantially the same and carrier current is supplied from the one oscillator. In the demodulator a complete suppression of the carrier is unnecessary as this is accomplished by the low pass output filter. For this reason, the small balancing grid condensers are omitted. In order to adjust the over-all gain of the channel, the demodulator is provided with an adjustable potentiometer graduated in two transmission unit steps, and in addition, fixed pads are provided for making further gain adjustments. The output of the demodulator is connected to the series winding of the voice-frequency hybrid coil.

The oscillator which supplies the carrier current to the modulator and demodulator is of the usual type. The tuning condenser includes a small variable unit for making small adjustments in frequency. Separate oscillators are used at the two ends for each channel, and as these are in no way connected together, it is occasionally necessary to make slight adjustments in order to keep the frequencies at the two ends substantially equal. The oscillators are very stable, however, and such adjustments are seldom required.

The individual channel filters are all of the band-pass type as previously indicated and have a free transmission range of approximately 2500 cycles. Outside

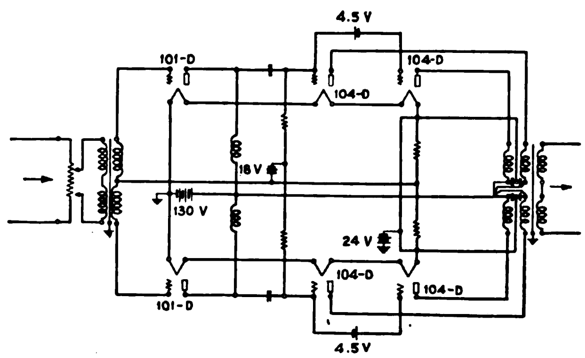

Fig. 9

this free range they have a high impedance so as not to act as a shunt for the other channels. They are all of substantially the same construction, although the constants of the component parts necessarily vary as the filters for the different channels transmit different frequencies.

The transmitting and receiving amplifiers, which are practically identical, are shown schematically in Fig. 9. They consist of two push-pull stages connected in tandem. Each half of the second or output stage con-

sists of two parallel tubes of high output capacity. In this way a comparatively high gain and a large energy output may be secured without overloading. This is very important as these amplifiers are common to all six channels and any tendency to overload would produce objectionable distortion and inter-channel modulation. In order to adjust the over-all gain for the entire system, each amplifier is provided with an input potentiometer.

As has been previously indicated, the transmitting and receiving circuits are joined to the cable by means of a hybrid coil. Probably the most difficult problem encountered in the installation of this system was the securing of an adequate balance. The difficulty of doing this may be better appreciated when it is realized that this balance must cover all frequencies from 3000 to 30,000 cycles, and must have a value of from 30 to 45 T. U., the higher value which represents an impedance unbalance of approximately one per cent being required at the upper frequency. In order to secure

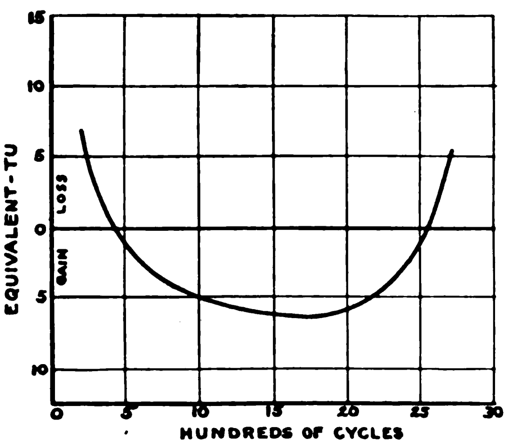

FIG. 10

such a balance, every part of the line circuit was matched by a similar part in the network circuit. All filters and transformers on the line side of the hybrid coil were duplicated in the network, and on the San Pedro side a 13-gage carrier-loaded cable pair was included in the network circuit between the office and the cable hut, and the inequality ratio transformer and basic network simulating the cable were located at the latter point. In addition to providing a balance within the carrier range, it was necessary at the San Pedro end for the network circuit to balance the cable within the voice-frequency range as a through-line repeater is employed on the voice-frequency circuit. Not only was it necessary to duplicate all parts in the line and network circuits but in addition they were carefully selected and paired so that the two parts associated would have, as nearly as possible, the same electrical characteristics. All wire pairs within the office which appeared in the carrier frequency circuits were individually shielded by means of a grounded metallic covering. The 13-gage carrier-loaded pairs in the cable joining the hut and the office were also individually shielded by means of a lead foil wrapping. This was done in order to preserve the balance and prevent cross-talk with another system which may be placed on the second cable at some future time.

Although extreme care was exercised in making the refinements described, the balance was still lower than was desired so that small variable auxiliary impedances were inserted at suitably chosen points in the line and network circuits. By the adjustment of these elements, it was found that the balance could be raised to any desired value for any particular channel, but that in so doing, the balance on some of the others would be impaired. By careful adjustment, however, it was possible to secure a balance for all channels within the range previously mentioned. As the transmission equivalent of the cable increases with the frequency, the over-all channel gains must be increased in the same manner in order that all circuits may have the same over-all equivalent. The networks were therefore arranged so that the higher frequencies would have the better balance, as in that way the margin of balance over gain could be made substantially the same for all channels. Since this margin should not be allowed to fall below a fairly definite minimum if the circuit is to have the desired stability, it is evident that the balance which may be secured determines the over-all gain which is possible. In this case the circuit equivalent for all channels between Los Angeles and Avalon was set at five T. U. As the loaded cable between Los Angeles and San Pedro is approximately nine T. U., it may be seen that the carrier system actually introduces a gain and performs the function of a repeater besides increasing the number of circuits. Fig. 10 gives a frequency characteristic of one of the channels which is typical of all of them. Balancing equipment has been provided for both cables as is shown in Fig. 5. With this arrangement, the carrier system may be operated over either cable. The transfer from one cable to the other is so simple that it can be made with practically no traffic interruption.

Signaling over the carrier channels is effected by means of 1000-cycle ringers which are connected to the circuits at the two terminals. As the ringing current is within the voice range, it is transmitted over the regular carrier channel so that no additional signaling equipment is necessary.

In order to insure satisfactory operation, all necessary testing facilities are included. Meters and keys are provided for measuring the voltages of the plate, grid and filament batteries as well as the plate and filament currents of all tubes. Individual rheostats are inserted in all filament circuits for making any adjustments that may be necessary. Alarms are provided to indicate any abnormal condition which might develop on any tube. Thermocouples and artificial lines have been conveniently arranged for checking the efficiency of all units such as the modulators and demodulators.

Jacks are located at suitable points so that any changes which may be necessary can be quickly made.

The general appearance of the carrier system may be seen from Figs. 11 and 12 which show the equipment at

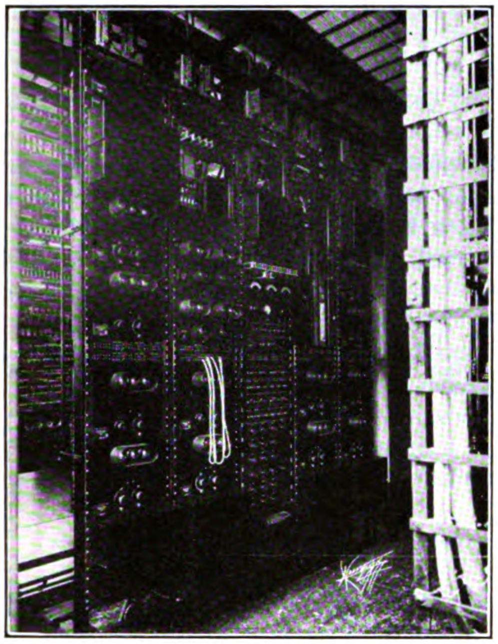

Fig. 11

San Pedro and Avalon respectively. Fig. 13 is an interior view of the San Pedro cable hut showing the cable terminals, together with the insulating trans-

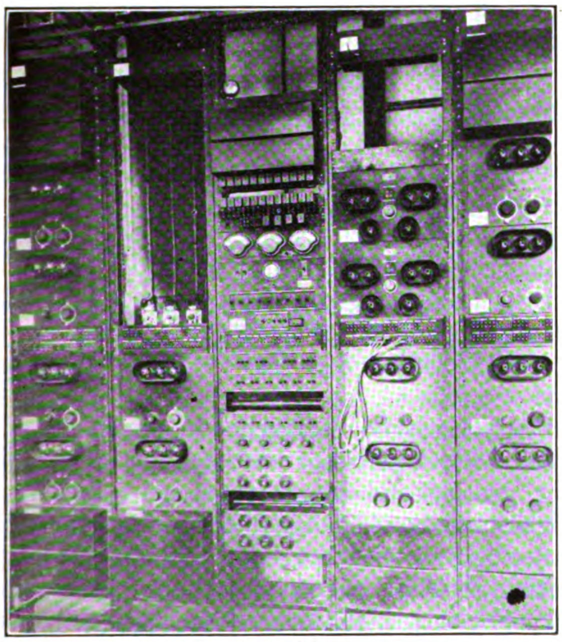

Fig. 12

formers, telegraph composite sets, and basis networks. Referring to the central office equipment, the first bay contains the equipment for two complete channels. At the top are the terminal strips for making all connections with the equipment below. On the next two small panels are mounted the hybrid coils and the other miscellaneous apparatus associated with the voice-frequency ends of the two channels. Below these are the modulator and demodulator band filters which are covered with dust proof cases. Next comes the modulator and demodulator panels for one channel. Below the two jack strips is mounted similar equipment for a second channel but arranged in reverse order. In the upper half of the second bay is located a small panel mounting the carrier hybrid coil and associated equipment. Below this appear the transmitting and receiving amplifiers. The lower half of the bay is similar to the lower half of the first one. In the third bay is mounted all the battery supply and testing apparatus. The first two units contain the battery retard coils. Below these are the alarm relays and auxiliary resistances. Next come the meters for measuring the tube currents and voltages, and below these are the

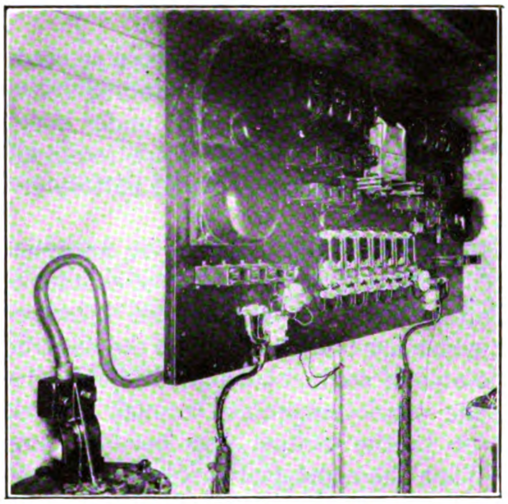

Fig. 13

thermocouples and artificial lines for making high frequency measurements. Below the jack strip are the keys for opening and closing the individual filament circuits used for measuring the plate and filament currents. Alarm lamps are also associated with each of the filament circuits. The fourth bay is similar to the second except that the upper half is vacant. As may be seen from the photographs, the amplifiers appear on the second bay at San Pedro and on the fourth at Avalon. The fifth bay is an exact duplicate of the first.

The new system has now been in successful operation for the past five months. In the light of its performance thus far, we feel assured that when more circuits are required a second system of six channels can be added to the second cable, thus providing a total of fourteen telephones and two telegraph circuits over the two single-conductor cables. Such a circuit group, we believe, will meet the traffic requirements for quite a number of years.

Temperature of a Contact
and Related Current-Interruption Problems

BY J. SLEPIAN[1]

Associate, A. I. E. E.

Synopsis.—*A formula is derived for the temperature rise of the last contact point of a pair of separating electrodes. The relation of this to arcing at a switch, brush drop, and commutation, is discussed.*

Experiments on the interruption of current by a switch in vacuum are described.

* * * * *

Low-Voltage Sparking at a Contact. It is a matter of common knowledge that when a circuit carrying current is opened at a pair of contacts, a flash of light which may be a spark or an arc results, even though the voltage of the circuit may be quite low. For example, if the blade of a knife is drawn across the terminals of a dry cell, a shower of sparks is thrown off, even though the cell gives only $1\frac{1}{2}$ volts. This phenomenon calls for explanation, since to start or maintain a discharge in gases or metal vapors in general calls for certain minimum voltages.

To start a discharge in a gas between separated electrodes requires in general several hundred volts, and to maintain an arc discharge, except under very special conditions, fifteen volts or more are required. How is it that the short-circuited, 1.5-volt battery gives such brilliant sparks?

Temperature at the Last Contact. An analysis of the thermal conditions at the last point of contact of a pair of separating electrodes suggests an answer to this question which has been raised. As the electrodes separate, the area of contact becomes smaller and smaller, so that the ohmic resistance through the electrode material up to the contact area becomes larger and larger. When the contact area reduces to a geometric point, this ohmic resistance becomes infinite. Hence, if a discharge does not start, all the voltage of the circuit must ultimately concentrate on this last contact. With metal electrodes, this means that there is an enormous concentration of current and power at the last contact so that a very high temperature is attained.

In the appendix, an approximate formula is derived for the temperature rise of a small contact between large electrodes when E volts are applied to it. It, is

$$T = \frac{E^2}{33.5\, k\, \rho} \tag{1}$$

where ρ is the electrical resistivity (ohms/cm.^{3}) and k the thermal conductivity (calories/cm.^{2}/deg. cent/cm.). Table I shows the temperatures for different electrode materials and voltages.

Thermionic Emission and Thermal Ionization. The very high temperatures indicated in Table I for metal electrodes permit a ready explanation of the discharge obtained at separating electrodes, for there are two ways known by which the minute gap between the electrodes will be made conductive by a sufficiently

TABLE I
TEMPERATURE RISE OF CONTACT

Electrodes	1–Volt	10-Volt	100–Volt
Metal $\rho = 10^{-5}$ $k = 1.0$	3000 deg.	3×10^5 deg.	3×10^7 deg.
Carbon brush $\rho = 0.01$ $k = 0.05$	60 "	6000 "	6×10^5 "
Autovalve arrester disc. $\rho = 100$ $k = 0.02$	0.015 "	1.5 "	150 "

high temperature. One is by thermionic emission from the electrode which is cathode. It is well known that at sufficiently elevated temperatures, current may be

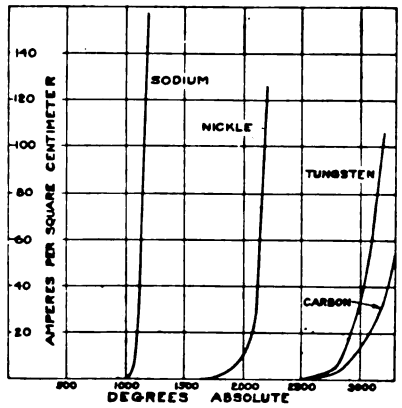

FIG. 1—THERMIONIC CURRENTS FROM METALS

passed from a cathode into space by means of emitted electrons. Fig. 1 gives the relation between thermionic current density and temperature for a few metals.

Another way in which a high temperature may make the space between the electrodes conductive is by thermal ionization of the gas or vapor there. Saha[2] showed that at sufficiently high temperature, gases will undergo a spontaneous ionization which will render them conductive. Fig. 2 gives for various gases the current density at the cathode as a function of temperature calculated from Saha's equation and the theory of

2. *Phil. Mag.*, **40, p. 472, (1920).**

Langmuir[3]. Since the vapor given off by a metal has the temperature of the metal, if the last contact is sufficiently hot, the vapor which it gives off will be highly conductive.

Examination of Figs. 1 and 2 shows that, to obtain high current densities, either by thermionic emission or by thermal ionization, temperatures in excess of the boiling points of the electrodes will be required. At first sight this presents a difficulty, as it may be thought that the rapid vaporization of the electrodes with the accompanying absorption of latent heat would prevent further rise of temperature of the contact. However, at any particular temperature, the rate of vaporization from a surface is finite, whereas the energy input density into the contact becomes infinite as the contact area approaches zero. Hence the vaporization cannot limit the temperature of the last contact point. The temperature of the last contact will be prevented from reaching the values of Table I only by current being diverted from it into the surrounding space or vapor.

Opening of Switch Carrying Current. The preceding

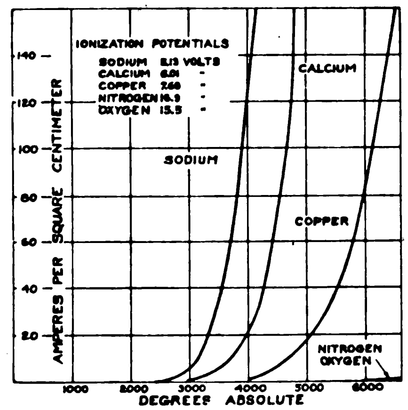

Fig. 2—Thermal Ionization Current Densities

considerations show that the opening of a switch with metal or other low-resistivity electrodes will always be accompanied by a discharge if there are more than a few volts in the circuit, and this will be true regardless of the medium in which the switch is placed, whether it be air, oil, or even high vacuum. If the circuit voltage is more than 15 or 20 volts, this discharge will change over into an arc discharge when the contacts become completely separated. This arc will be stable with very small electrode separation, but may become unstable when the electrode separation is increased.

As Table I shows, it is possible to increase the voltage necessary to start an arc at a switch contact by raising the electrical resistivity of the electrode material. This was mentioned in a paper on the "Autovalve Arrester"[4] and Fig. 3 is reproduced therefrom. The parabolic form of this curve is predicted by equation (1).

Switch in High Vacuum. Before these considerations were appreciated, the author believed that in a sufficiently high vacuum, arcless operation of a switch could be obtained even with relatively high voltage. Accordingly some experiments were carried out under his direction by Mr. W. J. Cahill. The tube was constructed as shown in Fig. 4. The contacts were held together by one of the supporting arms being a steel spring, and they were pulled apart by the action of the coil shown upon the iron armature

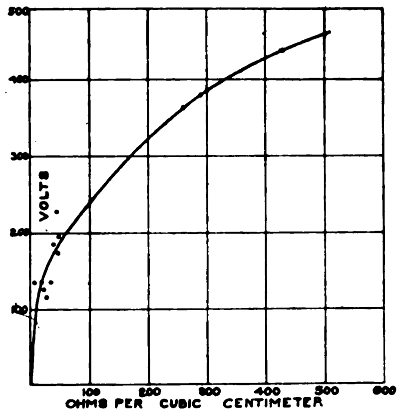

Fig. 3—Voltage to Draw an Arc by Contact

connected to the movable contact. The contacts could be changed, being held in place by a screw and nut.

The following combinations of electrodes were tried: Cu-Cu; Fe-Fe; Ni-Ni; Ni-Fe; Ni-Cu; C-Fe; C-Ni; C-Cu. The contact was placed in a 110-volt, d-c. circuit, with

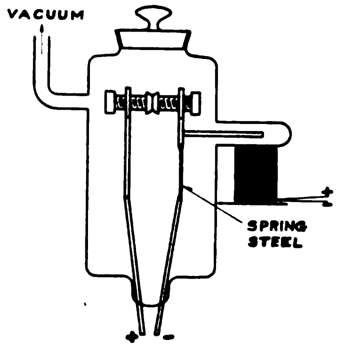

Fig. 4—Vacuum Switch

current controlled by a rheostat. In no case was inductance purposely introduced.

The tests showed that even with a vacuum of 0.001 mm., a luminous flash was produced with currents as low as one or two amperes. As the current was increased in strength, the flash became more intense, and appeared to persist for a longer time. The contacts quickly roughened under repeated service, and usually failed at from 40 to 50 amperes by welding together on closing. The best results were obtained with the carbon nickel combination, which could be made to work at 45 amperes at the rate of five or six times a minute.

The reason for the disappointing results is quite evident. It was impossible under the conditions of the

3. G. E. *Review*, 27, p. 449, (1924).
4. A. I. E. E. Journal, January, 1926, p. 3.

test to avoid a high temperature at the last contact. This meant volatilization of the electrode, and momentarily an arc carried in the electrode vapor. This arc would be very rapidly extinguished by the quick condensation of the electrode vapor, so that the principal obstacle to the practical application of the vacuum break was the consumption and roughening of the electrodes, and the difficulty of getting enough pressure upon the contacts to overcome the effect of this roughening.

Sparkless Commutation. The commutation of current in the ordinary d-c. generator and motor is perhaps the best example of continual opening and closing of heavy current circuits without arcing. It is interesting to consider present practise in the way of voltages and brush resistivities in the light of Table I. The voltage per bar on d-c. machines is usually from 15 to 20 volts, and in the commutating zone this is reduced by means of interpoles to less than a volt or two. Carbon brushes for d-c. service have resistivities from 0.001 to 0.01 ohm per cm.[3] Looking at the second example in Table I, we see that one volt gives a temperature rise of 60 deg., whereas 10 volts gives a prohibitively large temperature rise. Thus it appears that the limits for successful commutation are determined by the temperature of the last contact of brush and segment.

Contact Drop of Brushes. In the usual theories of commutation, the property of brushes considered is the contact drop of potential. That is, it is found experimentally that when less than a certain (usually rather erratically varying) voltage is applied between brush and commutator or slip ring, only a small current flows,

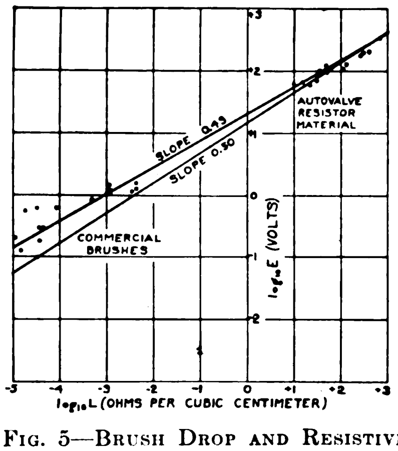

Fig. 5—Brush Drop and Resistivity

whereas if this voltage is exceeded very large current flows. The preceding paragraph suggests that this property of contact drop has a thermal origin, and that the contact drop is that voltage at which the relatively few points of intimate contact reach such high temperatures that conductivity is given to the space around them.

If this were so, then by formula (**1**), for brushes of the same thermal conductivity, there should be proportionality between the square of the contact drop and the brush resistivity. Mr. C. F. Wagner has collected data on commercial brushes, and also data on contact drop of high resistivity material such as is used in autovalve disks. These he plotted on double log paper as is shown in Fig. 5. The best straight line which can be drawn through these points has a slope of 0.43, indicating a quadratic law and supporting a thermal theory of contact drop.

Appendix

Calculation of Temperature Rise of a Contact

Let the line $O\,O$, Fig. 6, indicate a section of the face of one electrode, and let $A\,A$ be a diameter of

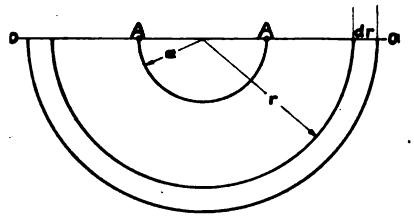

Fig. 6

contact spot, assumed circular. Then one-half of the ohmic drop across the contact will occur between the circle $A\,A$ and the rest of the electrode. It will make the calculation easier and introduce only a small error if we assume that the voltage $\frac{E}{2}$ is applied not at the circle $A\,A$, but between a hemisphere constructed on $A\,A$, and the rest of the electrode. Let the radius of this sphere be a.

The potential at the surface of this sphere is $\frac{E}{2}$, and within the electrode at a distance r from the center of this sphere the potential will be

$$V = \frac{E}{2}\,\frac{a}{r} \qquad (2)$$

The potential gradient will be

$$-\frac{\partial V}{\partial r} = \frac{E}{2}\,\frac{a}{r^2} \qquad (3)$$

The Joulian heat will therefore be

$$\frac{1}{4.19}\,\frac{1}{\rho}\left(\frac{\partial V}{\partial r}\right)^2 = 0.059\,\frac{E^2}{\rho}\,\frac{a^2}{r^4} \quad \text{calories/cm.}^3\text{/sec.} \qquad (4)$$

The heat evolved in a hemispherical shell of radius r and thickness $d\,r$ will be

$$2\,\pi\,r^2\,d\,r \times 0.059\,\frac{E^2}{\rho}\,\frac{a^2}{r^4} = 2\,\pi\,0.059\,\frac{E^2}{\rho}\,\frac{a^2}{r^2}\,d\,r \quad \text{calories/sec.} \qquad (5)$$

Letting k be the heat conductivity of the material and T the temperature at any point, the heat flowing into the shell from the inner surface will be per sec.,

$$-k \times 2\pi r^2 \left(\frac{\partial T}{\partial r}\right)_{r=r} \text{ calories/sec.} \tag{6}$$

The heat flowing out of the shell from the outer surface will be

$$-k\, 2\pi (r + d\,r)^2 \left(\frac{\partial T}{\partial r}\right)_{r=r+dr} \tag{7}$$

In the steady state, (5) = (7) − (6), hence

$$k\, 2\pi r^2 \left(\frac{\partial T}{\partial r}\right)_{r=r} - k\, 2\pi (r + d\,r)^2 \left(\frac{\partial T}{\partial r}\right)_{r+dr}$$

$$= 0.375\, E^2 \frac{a^2}{r^2} d\,r \tag{8}$$

Hence, dividing by $d\,r$ and passing to limit,

$$-2\pi k \frac{\partial}{\partial r}\left(r^2 \frac{\partial T}{\partial r}\right) = 2\pi \times 0.059 \frac{E^2}{\rho} \frac{a^2}{r^2} \tag{9}$$

Integrating with the boundary condition $T = 0$ and

$\frac{\partial T}{\partial r} = 0$ when $r = \infty$,

$$T = \frac{E^2}{33.5\, k\, \rho} \frac{a^2}{r^2} \tag{10}$$

Letting $r = a$,

$$T = \frac{E^2}{33.5\, k\, \rho} \tag{11}$$

RELATIVITY IN OBLIQUE COORDINATES

During the past three years Professor Vladimir Karapetoff has given talks on "Straight-Line Relativity in Oblique Coordinates" before several Institute Sections, as well as at some conventions of other societies, and has demonstrated his "blue and red" mechanical model of Einstein's fundamental relations. Institute members and readers of the JOURNAL will be interested to know that an article by Professor Karapetoff, containing a detailed elementary theory of restricted relativity in his oblique coordinates and a description of the model, has appeared in the August issue of the *Journal of the Optical Society of America*. Professor F. K. Richtmyer, Cornell University, Ithaca, N. Y., is the Business Manager of the *Journal*; the price of single issues, as long as they last, is 60 cents.

ELECTRICITY TO KEEP TRAINS SAFE

Making 7770 miles of railway in the United States safe against train collisions is no trivial task The accomplishment, as announced by the Interstate Commerce Commission July 28, marks the progress of the first quarter century of automatic train control in this country. This announcement registers the fact that after many years of heartbreaking experiment with all sorts of strange devices for stopping trains from running into danger, electricity has proved the only agency whereby this can do it. Hence the Commission has now given approval for train control schemes protecting 7770 track miles. How fast the Commission may order the rest of the country's mileage under automatic train control remains to be seen.

Most of the automatic control and stop devices in service consist of a magnet, about rail high, beside the track at the point where it enters each signal block. Suspended from each locomotive is another type of magnet. When they pass, a flash of electric current opens a relay which actuates an air mechanism in the engineer's cab so as to set the brakes at once and bring the train to a stop.

It is provided that the engineer can forestall this brake setting by touching a button or small lever as his engine passes over each of the track magnets. He must, therefore, be alert at all times or his train will be taken out of his hands and brought to a standstill whether or not there is immediate danger ahead. This is electricity's guarantee that train operation in the future will be safer.

In 1914 the first permanent installation of a device to stop trains automatically was made on the Chicago & Eastern Illinois which runs south out of Chicago. Since then a vast amount of study and test has produced four or five general types which are now in use. Some exercise only intermittent control over trains operating only at given points. Others are continuous. Some merely apply brakes once, so as to bring a train to a stop with what is known as a "service" or ordinary application of air. Others begin by slowing down a train at one point, setting the brakes up tighter if the train passes another point and finally clamping down the shoes for an "emergency" stop.

Nearly all of them operate in connection with the block signal system. Since electric block signals, after long years of use, have proved that they fail only once in 40 million operations, the attached train control device is not going to suffer much instability by reason of signal system failure. But none of the devices that have been approved are considered beyond the possibility of improvement. Thus the 7770 miles of track and the 3700 engines equipped with the new appliances are considered a vast experimental laboratory to prevent many wrecks and save many lives while loading up to a closer approach to perfection in automatic train control.

Measurement of Transients by the Lichtenberg Figures

BY K. B. McEACHRON*

Member, A. I. E. E.

Synopsis.—*The paper gives the results of a comprehensive study of the effect of transients on the size and appearance of Lichtenberg figures. Sixteen different rates of voltage rise were used, varying from about 20 minutes to 0.1 microsecond to reach a crest value of 25 kv. Results were obtained with transients the crest voltages of which ranged from 5 to 25 kv. The steeper wave fronts were checked with the Dufour cathode-ray oscillograph.*

Calibration curves are given, showing that the positive figures are not much affected by changes in wave front, while the negative figures vary considerably with changes in wave front, especially at the lower voltages.

The positive figures are divided into three types according to their appearance which is found to depend on the rate of voltage rise. It is concluded that for most conditions the size of the positive figures will give a determination of the crest voltage of the applied transient to within approximately 25 per cent.

UNTIL the cathode-ray oscillograph was applied to the measurement of transient phenomena, engineers were unable to determine accurately by experiment the form of a transient voltage or current, the wave front of which occupied only a few millionths of a second of time. Such transients may occur on transmission or distribution circuits during periods of disturbance,—as, for instance, during a lightning storm,—and may cause considerable damage to unprotected apparatus.

Although the cathode-ray oscillograph can be arranged to show the volt-time, ampere-time or volt-ampere relations, yet there is need of a device which may be used to record these disturbances with fair accuracy at the same time involving a small amount of equipment so that a large number of them can be spread over the systems of the country at a comparatively small cost.

Lichtenberg Figures

If a sheet of insulating material, such as hard rubber or glass, is placed on a metal sheet and an electrode of any shape is allowed to rest on the upper surface of the insulating material, a Lichtenberg figure will be formed by the application of voltage between the electrode and the metal sheet. The figure may be made visible by the use of chalk dust which may be applied to the insulating surface before or soon after the application of voltage. A permanent photographic record of the figures can be made by placing a photographic film between the electrode and the insulating plate with the emulsion side in contact with the electrode.

A large amount of work has been done with these figures in the effort to discover their exact meaning and the variables which control the figures. Among those who have experimented with them may be mentioned P. O. Pederson[1], Toepler[2], Przibram[3], and others[4], all of whom have made notable contribution to the solution of the problem of the proper understanding of the Lichtenberg figures. Peters[5] applied the Lichtenberg figures to the study of transmission line transients, and suggested means for making connections to the transmission line to determine supplementary information about the transient. In order that the surges might be recorded with respect to time, Peters made use of a moving electrode, the complete instrument being termed the klydonograph.

Cox and Legg[6] later described some of the results obtained on transmission systems by using the revolving electrode type and described an improved klydonograph which made use of a roll film. As a result of tests with the klydonograph, Cox and Legg concluded that the relation between the size of figure and crest value of the transient was not appreciably influenced by the wave front between the limits represented by a 25-cycle wave and a wave whose crest is reached in 5 microseconds.

All investigators have found that the positive and negative figures were different in appearance and that when the electrode was positive a larger figure was formed than when the electrode was negative. At times the figures are complicated by tree-like growths which have been ascribed by some to over-loading the film, but this does not always seem to be the case as they are sometimes found at lower crest voltage than that which at other times does not produce them. In the practical interpretation of the figures, it seems to be necessary to neglect these effects until their meaning is known.

Effect of Wave Front

The author is not aware of any systematic work that has been done having for its object the calibration of the figures with respect to the form of the voltage transient. Up to the present time, the figure has been regarded as not being much affected by rate of voltage application and therefore the present investigation was undertaken to determine, if possible, the relation between the size of the figure and the rate of voltage application, as well as the crest value.

A transient, such as that shown in Fig. 1, consists of three major parts; the front, and the part we may call

---

Presented at the Pacific Coast Convention of the A. I. E. E., Salt Lake City, Utah, Sept. 6-9, 1926.

the body for want of a better name, and the tail. In the simple wave of this kind, presumably each of these parts may play a role in the production of the Lichtenberg figure. The investigation to be described in this paper is concerned altogether with the front of the wave, as the rate of voltage rise and the crest value of voltage appear to be the dominant factors in determining the characteristics and the size of the figures.

To make the work as complete as possible, tests have been carried out covering a wide range of wave fronts, the slowest being slower probably than any ever obtained in practise, while the fastest are probably as fast as any that ever occur in service, being but a few hundred feet in length. Sixteen different wave fronts at five different voltages were used and, except at the very slowest, oscillograms were taken of each voltage application. Every care was taken with the shorter waves to eliminate the effect of reflection and to keep the oscillation on the wave front to a minimum. This has been possible only through the use of the Dufour cathode-ray oscillograph[7] the voltage dividing system of which was connected directly across the electrodes producing the Lichtenberg figures, using leads only two or three feet in length.

It would have been desirable perhaps to have used

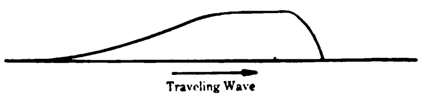

Fig. 1

a wave throughout having an initial value of de/dt kept constant up to the crest value of voltage; yet, with the steepest wave this limitation would have complicated the test seriously without adding much to the practical value thereof.

Voltage and Time Calibration

The sphere-gap was used as the primary means of determining the crest value of voltage of the transient. With the slower waves the crest potential of which was reached in times longer than 10 seconds, it was possible to check the sphere-gap against a static voltmeter and also against meters located in some of the low tension circuits. The time for the slow waves was conveniently determined with a stop watch.

Within its range, the electromagnetic oscillograph record gave the time calibration of the transient, the time being based on a 60-cycle wave recorded on the same film. The transients above the range of the electromagnetic oscillograph were recorded with the Dufour cathode-ray oscillograph with time scale calibrated by the use of a wave meter. With the type of circuit used, the wave front could be calculated quite accurately and, except for the oscillations which in most cases were successfully removed, the oscillograms checked the calculations within the experimental error in practically every case except for the steepest waves where stray capacities become of importance. In all such cases, the oscillogram after being checked carefully was assumed to be correct.

Circuit Arrangements

The slowest waves were obtained with the circuit given in Fig. 2 in which the condenser C was charged slowly by the use of a motor driven regulator connected in the primary of the charging transformer. The

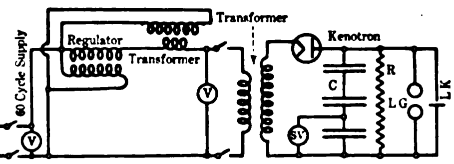

Fig. 2—Connection Diagram for Slow Waves Using Motor-Driven Regulator
Time to reach crest 20 min. 55 sec.

reduction gears were such that, for the longest wave front, 22 minutes were required to reach a crest value of 25 kv. The limit of this method was about a 12-second front.

Other circuits used were similar to that shown in Fig. 3, in that a capacity C_1 was allowed to discharge in another capacity C_2. By varying the amount of capacity employed, together with appropriate values for series resistance connected between the condensers, the desired changes in wave front were obtained. A sphere-gap was used in series between the two condensers for the steeper waves, while with the slower waves, using this type of circuit, a kenotron was connected between the two condensers and the transient initiated by heating the filament at the proper time.

Considerable difficulty was experienced with the steepest waves in decreasing the amount of oscillation on the wave front. The rate of voltage rise was ex-

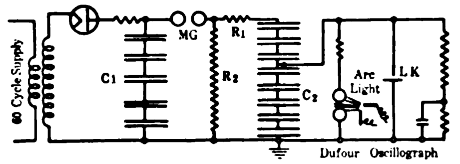

Fig. 3—Connection Diagram for Voltage Transients
Time to reach crest 1.0 sec.—0.1 microsecond

tremely rapid, being 100 kv. per microsecond. The final circuit used was physically quite small with all connections made with conductors having a high uniform resistance to aid in damping out the oscillations. Such a wave front is shown in Fig. 13.

Results—Effect of Changes in Wave Front

The Lichtenberg figures were taken, using a piece of plate glass 20.3 cm. × 25.4 cm., 3.8 mm. thick, with a cylindrical brass electrode 1 cm. in diameter in contact with the photographic film. The films, which were East-

man's super speed portrait films, were placed on the glass plate with the emulsion side in contact with the electrode. On the reverse side of the glass plate and opposite the electrode was a lead foil so connected that the electrode and foil was of opposite polarity. The parts were arranged in a light-tight box with the electrode projecting, to which connections were conveniently made, as shown in Fig. 4.

The results are plotted in terms of the radius of the

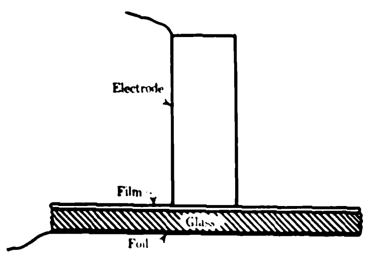

FIG. 4—ARRANGEMENT OF PARTS OF LICHTENBERG CAMERA

figure plotted against slope of the wave front in volts per microsecond for five voltages, 5.5 kv., 9 kv., 12 kv., 17 kv., and 25 kv. (All voltages are crest values). The curves for the positive figures are given in Fig. 5 and for the negative figures in Fig. 6.

Notwithstanding the precautions taken to control all of the known variables, the plotted points show considerable variation which is most marked with the shorter waves and at 17 kv. and 25 kv. For all voltages, the positive figures increase in size as the wave becomes steeper, until a rate of rise of between one kv. per

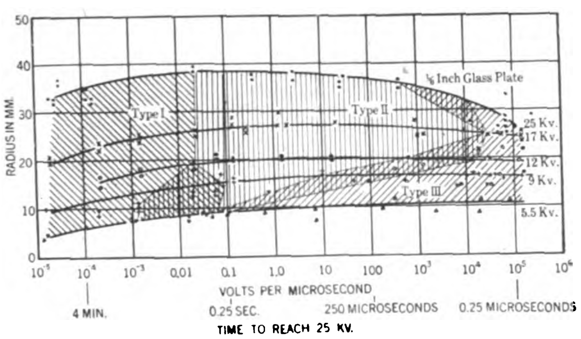

FIG. 5—VARIATION OF POSITIVE LICHTENBERG FIGURES FOR DIFFERENT CREST VOLTAGES AND RATES OF VOLTAGE RISE

microsecond and 10 kv. per microsecond is reached. With wave fronts steeper than this, which corresponds to about a 60-cycle front, the lower voltage figures remain constant in size while the 17-kv. and 25-kv. figures decrease somewhat at the steepest points. Fig. 5 has been divided into three zones which are determined from the appearance of the positive figures and will be discussed in connection with the different types of figures.

The negative figures were less satisfactory at the slow rates of voltage rise than were the positive figures, it sometimes being difficult to separate what appeared to be corona from the Lichtenberg figure. The results do indicate a rather abrupt increase in the size of the negative figure between 0.001 volts per microsecond and 0.01 volts per microsecond. As the voltage rises faster and faster, the negative figure increases in size, the greatest percentage change occurring with the lower voltages. For instance, the figure at 5.5 kv. increases from about 0.2 mm. to 13. mm. when the front changes from 0.01 volts per microsecond to 100,000 volts per microsecond. At 9 kv. the radius changes from 0.5 mm. to 2.4 mm. when the wave front changes through a similar range. The radius at 25 kv.

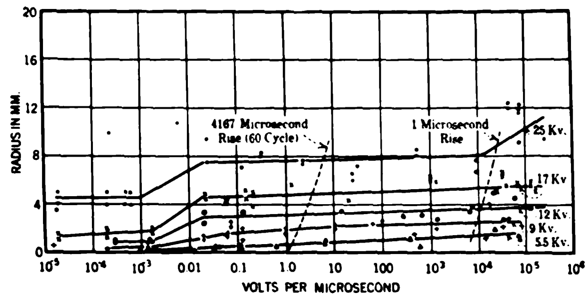

FIG. 6—VARIATION IN SIZE OF NEGATIVE LICHTENBERG FIGURES FOR DIFFERENT CREST VOLTAGES AND RATES OF VOLTAGE RISE

shows a sudden increase for fronts steeper than 10,000 kv. per microsecond.

Using the curves in Figs. 5 and 6 as representing the average values from the data, calibration curves have been drawn as given in Fig. 7. These curves show that the average positive figures are not appreciably affected by wave front except for the highest voltage and steepest front. The variation between the slowest and fastest waves for the negative figures is much

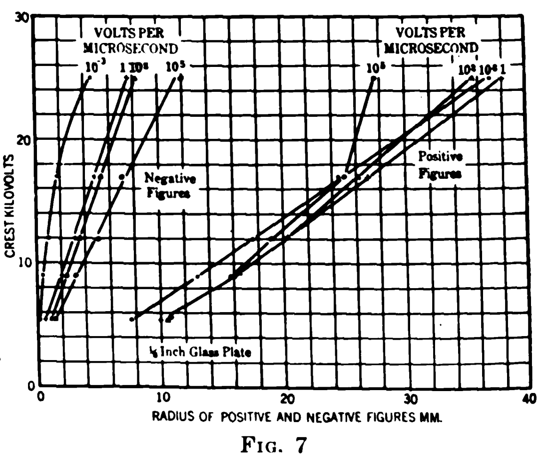

FIG. 7

greater than for the positive and should be considered when determining the voltage from a negative figure. At 17 kv., an increase of nearly 50 per cent takes place when the wave front changes from that corresponding to a 60-cycle wave to one which rises to 17 kv. in 0.1 microsecond, while, for lower values of crest voltage,

the variation is much greater. Some idea of the wave front may be determined by the comparative sizes of the positive and negative, but there is sufficient variation among pictures at the same wave front to make such a procedure doubtful for everything except very approximate results.

Appearance of the Figures

It is possible to divide the positive figures according to appearance into three definite type forms with respect

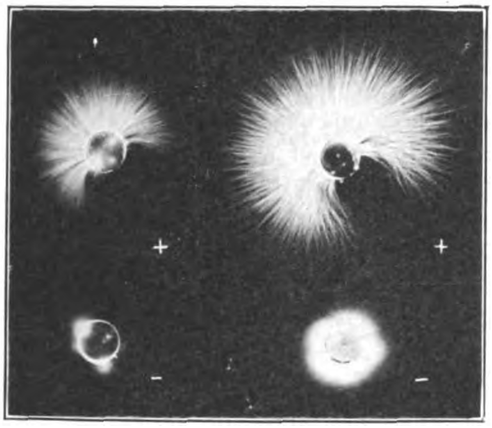

Fig. 8—Lichtenberg Figures Produced by a Very Slow Rise in Voltage (Type I—Positive Figures)

A. *P L*—20519 *R* 17 kv. in 840 sec. B. *P L*—20512 *R* 25 kv. in 85 sec.

to rate of voltage rise on the electrode. These three types are shown in Figs. 8, 9, and 10, type I being the slowest while type III represents the greatest rates of voltage rise.

Type I consists of fine straight lines emanating from

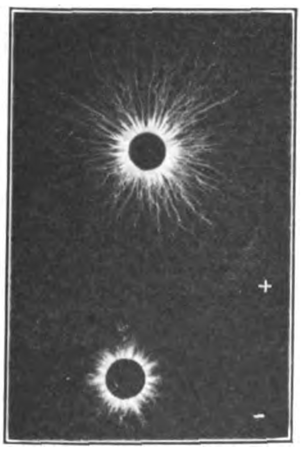

Fig. 9—Lichtenberg Figures Produced by a Fast Transient (Type II—Positive Figure)

P L—20573 *L*—21.6 kv. in 48 microseconds

the center and perhaps extending only partially round the entire electrode. The appearance is much like that of fine hair being blown out by some force at the center. As the rate of voltage rise becomes smaller, both the number of hairs and their length decrease until, in one case with a 6-second wave at 5.5 kv. crest, only five hairs were found, their length varying from 7.5 mm. to 8 mm. However, with a 6-minute front at the same crest voltage, the length of the hairs had been reduced to 4 mm., while the number of hairs had increased to perhaps 30 or 40, bunched in two or three small tufts. Some representative type I, positive figures are shown in Fig. 8.

The negative figures become smaller and smaller with decreasing rates of voltage rise until they disappear altogether or become so indefinite and indistinct that they cannot be measured.

In appearance, type II figures are quite different from type I being characterized by crooked lines which are likely to have sharp turns or elbows near the ends and usually split or branching. Sometimes short projections like thorns appear, but these belong more

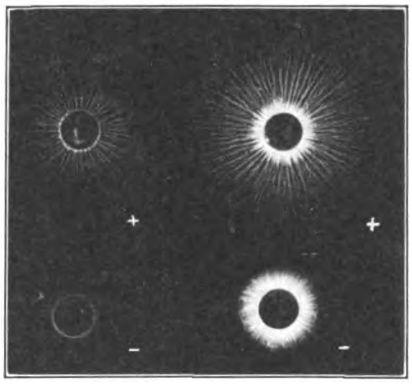

Fig. 10—Lichtenberg Figures Produced by Very Fast Transients. (Type III—Positive Figures)

A. *P L*—20607 *L* 7.3 kv. in 0.1 microseconds. Produced by transient shown in Fig. 12 B. *P L*—20605 *R* 17.8 kv. in 0.15 microsecond. Produced by transient shown in Fig. 13

to type III than to type II. Fig. 9 shows a typical figure of this type. The so-called slips are quite likely to have type II figures at the ends, even though the body of the figure is of another type. It should be noticed, also, that with type II figures, there is almost no crossing of lines even though the voltage was sustained for an appreciable length of time compared to the wave front.

The figures which have been called type III exhibit characteristics very different from either type I or type II. Type III figures as shown in Fig. 10 are recognized by their straight radial lines, having rather broad bases with splits and thorns. In type III figures, the lines do not cross and once seen it is not difficult to recognize a figure of this type indicating as a rule waves of quite steep fronts.

The voltage and frequency at which the three different types of figures are found are shown in Fig. 5 where the three types of figures are indicated. Some overlapping takes place where two types are found in the same

figure. At the 5.5 kv., it is interesting to note that the range of wave fronts over which type II figures appear is very small, and in fact they are not found alone at this voltage, always being mixed with either type I or type III figures.

The negative figures undergo considerable change in appearance as the wave front becomes steeper, but the change is gradual and it is not possible, using the data now available to draw definite limits or to divide them

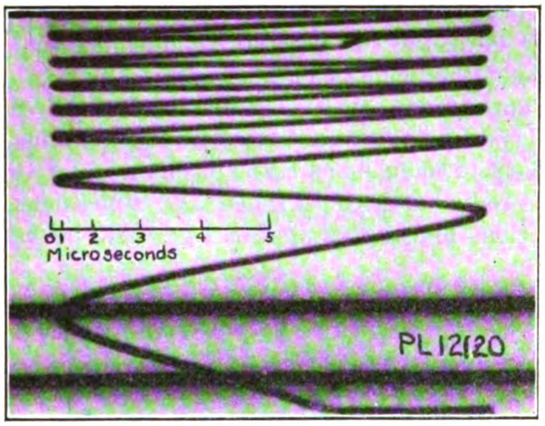

Fig. 11—Dufour Oscillogram of Transient Voltage
21.6 kv. in 48 microseconds. Corresponding to Lichtenberg Figure shown in Fig. 9.

into types. In Figs. 9 and 10 representative negative figures are given, corresponding to the wave fronts shown in Figs. 11, 12 and 13. The slow negative waves as in Fig. 8 show a rather hazy indefinite outline

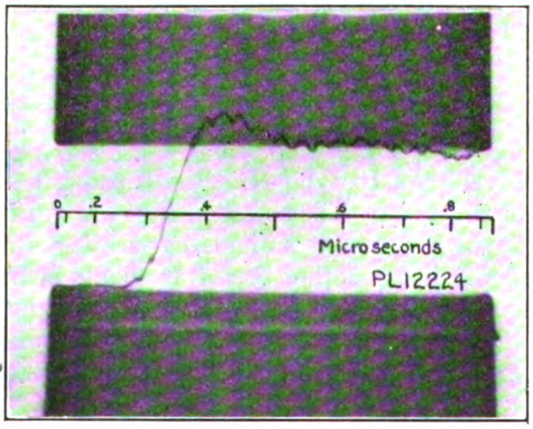

Fig. 12—Dufour Oscillogram of Transient Voltage Retouched
7.3 kv. in 0.1 microsecond. Corresponding to Lichtenberg Figure shown in Fig. 10.

with a tendency to concentrate in tufts. These figures are difficult to measure and look much like photographs of corona.

With steeper waves, as in Fig. 9, radial sectors of exposed film appear with more or less definite unexposed space between. Superimposed, many short crooked lines are frequently found not often extending beyond the exposed radial portion. While this form of negative is easier to measure than that obtained with the very slow waves, yet the limit of the figure is not sharply defined.

Very short waves produce a negative as in Fig. 10 in which the radial sectors are clearly defined and the limit of the figure is quite definite. Not only are the sectors more sharply defined but the width at the circumference of the figure is reduced, the space being occupied by a larger number of sectors. While crooked lines superimposed on the figure appear frequently, they are often less prominent than those seen with slower waves as in Fig. 9.

Oscillograms

Three oscillograms are shown in Figs. 11, 12, and 13 to indicate the form of waves actually applied to the photographic film when taking the Lichtenberg figures.

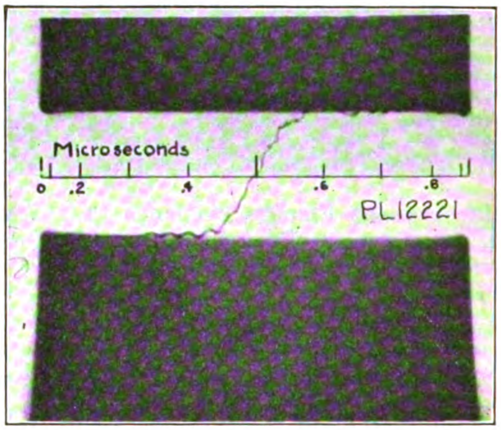

Fig. 13—Dufour Oscillogram of Transient Voltage
17.8 in 0.15 microseconds. Corresponding to Lichtenberg Figure shown in Fig. 10.

These oscillograms were taken with the Dufour cathode-ray oscillograph and show some of the wave fronts used in making the Lichtenberg figures shown in Figs. 8, 9, and 10. In Fig. 11 is shown an oscillogram of the wave taken at the same time as film PL-20573L shown in Fig. 9. This film shows that the voltage rose to its maximum (21.6 kv.) in 48 microseconds the average rate of voltage rise being 450 volts per microsecond while the maximum rate is 1800 volts per microsecond. The film shows that the final voltage was attained without oscillation and that the voltage dropped very slowly compared to the front after reaching its crest. All of the waves used in this investigation, as a rule, had long tails as compared with the front, so as to be sure that the tail did not disturb the results.

As the time to rise to maximum voltage was reduced, the difficulty of getting a smooth wave increased, but that a fair degree of success was finally attained is seen in Fig. 12. This film shows that a voltage of 7.3 kv. was reached in 0.1 microsecond which is equiva-

lent to an average rate of rise of 73,000 volts in one millionth of a second (Lichtenberg figure PL-20607L, Fig. 10). While some oscillations are present, their amplitude does not appear to be sufficient to make them a matter of importance.

Another film in which a still greater rate of voltage rise is recorded is shown in Fig. 13. Here the average rate of rise of potential is 120,000 volts per microsecond. The Lichtenberg figure corresponding to this wave front is shown in Fig. 10 film PL-20605R.

Films similar to these were taken for every voltage application when making Lichtenberg figures and it can be stated that for waves having a longer front than 10 microseconds any oscillations which were present were negligible and that for the shortest waves such oscillations did not exceed 20 per cent of the crest voltage.

It is interesting to note that when working with these figures the impression is gained that the presence of oscillations increases the distinctness and clarity of the figures and that this is particularly true of the negative. While this as yet is only an impression, yet the cleanest figures always were associated with the waves having oscillations on the wave front.

Conclusions

As a result of this investigation, it can be definitely stated that the size and appearance of both positive and negative Lichtenberg figures are dependent on the wave front as well as on the crest voltage.

Throughout the range of wave fronts probably found in service, the size of the positive figure is not much changed by a change in wave front only, except at voltages close to the upper limit of potential where a decrease in the size of figure is indicated with very abrupt fronts.

The positive figures may be divided into three type forms which are partly determined by wave front and partly by the value of the crest voltage. It is possible to gain some idea of the steepness of the front from the appearance of the positive figure.

The size and appearance of the negative figures are considerably affected by changes in wave front, the steepest waves always giving the largest figures. The percentage change with a constant crest voltage applied is greatest for the lower voltages. The change seems to be great enough so that it cannot be neglected. The negative figures change in appearance with increasing steepness of wave front, but the changes are so indefinite that it is only possible to state that a particular negative figure probably represents a fast wave or a slow wave.

No value is given for the possible variation in radius of figures with identical wave front from the average, although the usual variation is probably not greater than 25 per cent. Occasionally, one will be found where the figure is 50 per cent or more, larger or smaller than the average for that particular wave. There seems to be some tendency for the greatest variations to occur with the steepest wave fronts.

The curves which have been given apply to apparatus of certain characteristics and should not be applied to figures taken with a different dielectric than used here or for other different conditions. It seems likely, however, that similar results will be found with other apparatus constants although the values would be different.

Additional work is being done with the cathode-ray oscillograph in an effort to determine how the Lichtenberg figures grow and the reasons for the various characteristics which they exhibit.

The author wishes to express his appreciation of the work of E. M. Duvoisin and T. Brownlee, who have supplied all the figures and most of the oscillograms, and to E. J. Wade for his valuable assistance, particularly in arranging the circuits so as to avoid oscillation.

CORRESPONDENCE

To the Editor:

On page 783 of the issue of the Journal of the A. I. E. E. for August, 1926, there is an obituary notice of the late Charles E. Scribner, from which I quote as follows: "Mr. Scribner was a well-known electrical inventor, having taken out almost 500 patents during the course of his active service. After the death of Steinmetz, he was credited with holding more patents in the electrical field than any other man, save his friend, Thomas A. Edison," etc., etc.

In the interest of accuracy, I wish to state that Professor Elihu Thomson, of the General Electric Company, has approximately 700 United States patents alone, most of them, of course, relating to the electrical field.

John A. Mc Manus

Electrical Machinery

Annual Report of Committee on Electrical Machinery*

BY B. L. BARNS, Chairman of Subcommittee on Annual Report

To the Board of Directors:

The activities of this committee during the past year have been carried out on a plan of organization comprising a number of subcommittees as outlined in Mr. H. M. Hobart's report to the President and Board of Directors on the Development of the Activities of the A. I. E. E. Technical Committees under date of January 19, 1925. This report is under consideration by the Committee on Technical Activities to determine the advisability of recommending it in whole or in part for all of the technical committees. The scope of the Electrical Machinery Committee's activities has been based on the recommendation contained in a report made by Mr. A. W. Berresford as chairman of a Special Committee to Review Technical Activities of the A. I. E. E. under date of January 23, 1924.

During the past year the Electrical Machinery Committee has been more active in standardization work. A subcommittee on standardization has been organized under the chairmanship of Mr. J. C. Parker which is functioning in an advisory capacity to the Institute's Committee on Standardization in matters concerning electrical machinery. The committee on Electrical Machinery, through a subcommittee under the chairmanship of Prof. V. Karapetoff, is also sponsoring research work affecting standardization and advancements in the art and is collaborating with the Committee on Research.

That part of the Electrical Machinery Committee's work which has resulted in the most tangible accomplishments has been the procuring and reviewing of suitable papers on various subjects which have been presented under the auspices of this committee at the regular and regional meetings. The following table shows the number of papers under different classifications that have been presented during the year.

Factors which affect design of electrical machinery...	5 papers
Generator design and construction................	8 papers
Motor design and construction.....................	4 papers
Transformer design and construction..............	2 papers
Total........................	19 papers

Presented at the Annual Convention of the A. I. E. E., at White Sulphur Springs, June 21-25, 1926.

In preparing a review of the development or advancement of the electrical machinery art one is inclined to turn first to those new types of machines that have developed and those machines which represent new records for high rating or size or voltage. The research work, whether it be mathematical, chemical, or physical, by which new types and high ratings are made possible is less spectacular but of fundamental importance. The enumeration of new high water marks of ratings may not of itself appear to be an index of an advancement of the art but there are often many details and problems involved in the successful design and manufacture of such machines involving real pioneer work. Nor is all the engineering pioneer work confined to setting new records of large size. If we would but examine them carefully we would find research and ingenuity written all over the smaller apparatus that we see about us every day and take for granted.

It is, of course, beyond the scope of this report to record even briefly the solution of the many problems involved in the perfecting of new developments, for time and space would not permit, nor is such detailed information available for that purpose. In considering the remarkable things that have been accomplished in building huge machines we should not overlook the importance of the development and improvement of the small apparatus upon which the expansion and growth of the electrical industry is so largely dependent.

Again we take a considerable measure of satisfaction in recording new attainments reached in higher ratings of machines which have been put into successful operation. New records have been made for large capacity all along the line. Larger ratings than ever before obtained have been built in transformers, synchronous motors, induction motors, d-c. motors, horizontal-shaft alternators and turbo alternators.

The following review is classified under headings for convenience in preparation and reference and an attempt has been made to include under each a bibliography of the more important articles that have been published during the year. An attempt has also been made to cover the more important developments that have taken place in Europe as well as in America (the United States and Canada). An apology is offered if important articles or developments have been omitted. Such omissions are entirely accidental.

RESEARCH

This committee now has the following subjects under consideration and it is probable that as investigations advance sufficiently to mention definite results they will be described in the form of papers for presentation at

Institute meetings. These topics are mentioned not so much to record the actual progress made by the Committee as to indicate problems of importance brought to the Committee's attention.

Effect of Altitude on the Dielectric Strength of Insulations. An investigation has been proposed to determine whether it is desirable to draw a distinction between apparatus that is to be used at sea level and high altitudes as regards the insulation tests.

Influence of Expansion and Contraction of Conductors on Insulation Deterioration in Long Machines. This subject has already received a great deal of attention and some valuable experimental work has been done. This subject is becoming of greater importance with the increasing capacities of turbo alternators. Further investigation has been suggested as desirable.

Surge Tests of Insulation. An investigation of this subject is being undertaken to determine whether it is desirable or practical to standardize a test of this sort on the insulation of machines that may be subjected to transient high-voltage conditions.

Hot Spots in Cores of Alternators. Observations made by engineers in Europe have indicated that higher temperatures may be reached in the slots at the ends of a turbo generator core than in the slots at the center of the core. Manufacturers in the United States have reported that they have been unable, from tests made on machines of American make, to substantiate this statement. This may be due to the difference in the design of end windings in Europe and in America.

Evaluation of Conventional Losses. The present A. I. E. E. Standards assign conventional values to certain losses that are known to exist. It is felt that methods should be devised by which these losses may be determined by tests so that the design and tests may be reduced to a more exact science and due credit may be given to designs that are especially meritorious in this respect.

Calorimetric Method of Determining Losses in Alternators. The feasibility of determining the losses and efficiency of alternators by calorimetric methods which are based on the temperature rise of the cooling medium is being investigated.

Stability of Alternators. As distribution systems increase in size and the use of long, high-voltage transmission lines is extended, the subject of stability of generators becomes of greater importance. A study of the possibility of the evaluation or definition of generator stability is being made so that this characteristic may be specified.

Relation between Dielectric Tests on New and Used Machines. This subject has arisen from a consideration of recommended practise in checking the condition of the insulation of a machine that has been in operation for some time.

Non-Destructive Physical Tests on New and Used Insulation. Physical tests of insulation have been suggested as being desirable; accordingly, the subject is being investigated.

During the past year research work has been done on the following subjects that come within the scope of this committee's activities:

Effect of Altitude on Ratings of Electrical Machinery. This investigation was undertaken for the purpose of providing a satisfactory revision of the present A. I. E. E. rules which have been recognized as not being entirely satisfactory.

Copper Eddy-Current Losses. A theoretical foundation for the calculation of no-load copper eddy-current losses in machines has been presented.

Motor Band Losses. Methods of calculating losses in the binding bands of armatures of direct-current machines have been made practicable.

Heating Curves of Electrical Machinery. A further study of the prediction of the heating curves of machines has been presented.

Alternator Short Circuits. The calculation of the transient phenomena resulting from short circuits of the armature windings of alternators has been a subject of study for many years and an accurate method of predetermining the value of the short circuit current is becoming more and more important as the generating capacity of power systems increases from year to year. Two papers have been presented to the A. I. E. E. during the past year dealing with this subject. One of these papers treats the subject on the basis of Kirchoff's law that the vector sum of all the currents at a junction is equal to zero. The other paper is based on the constant linkage theorem, viz: "In a circuit having zero resistance the algebraic sum of the flux linkages of the circuit must remain constant."

Measurement of Stray Load Losses in Alternators. A paper has been presented which has suggested a different method of determining stray load losses than that specified in the present standards, and results of tests have been given.

Ventilation of Turbo-Alternators. During the year this work has been carried forward to a conclusion by the use of small models. Previous calculations and empirical formulas have been checked so that now a complete solution of the complex problem of measuring static pressures in a fluid moving at considerable velocity can be successfully obtained.

Theory of the Synchronous Induction Motor. This subject has received considerable attention in Europe and a number of excellent treatises have been written.

Hydrogen as a Cooling Medium. A further investigation of the problems incident to the use of hydrogen as a cooling medium has been undertaken.

Characteristics of Synchronous Machines. Blondel's theory of two reactions has been extended to include the effect of harmonics and of field excitation in the quadrature axis.

VENTILATION OF ELECTRICAL MACHINERY

Ventilation, one of the fundamental considerations in the design of electrical machinery, has been a subject of very active study and experimentation. Because the design of turbo alternators involves a relatively greater need of a knowledge of the phenomena incident to the flow of gases through irregular passages, experimental work has been carried out to determine the forms of fans, bafflers and internal ducts which would give the desired cooling effect with a minimum of windage losses by introducing into new machines alternative ventilation schemes which were tried out when they came to test. In this way much valuable and accurate information has been obtained which has been free from some of the uncertainties of theoretical considerations of a very complicated problem. Nevertheless, considerable help has been obtained by building small models and testing them under laboratory conditions to check and verify principles that have been deduced by a theoretical treatment of the problem. Models have been constructed to represent the vent ducts and air passages in the stator core of a turbo alternator and tested to determine the drop in pressure in the several parts of the passage ways. In this way data was obtained by which close approximation can be made of the amount of pressure required to force a given quantity of air through a given machine. Other models have also been tested to determine the most efficient shapes of slot retaining wedges in stators and the best arrangement of spacers in the internal ventilation ducts. All of this work has contributed toward better designs not only of turbo alternators but also of other types of machines.

This committee's report of last year made mention of an investigation into the use of hydrogen as a cooling medium for rotating machinery. The results of this have been published and this method seems to have many advantages that would make it desirable for commercial application and some operating engineers are looking forward to the time when it will be found feasible to use hydrogen for this purpose. Some of the new machines that are now being purchased are being arranged so that they may be readily adapted to the use of hydrogen when the problems peculiar to its use are finally solved.

A few years ago the recognized need of providing clean air for the ventilation of machines, especially large capacity turbo alternators, was met by the use of air cleaning and air washing apparatus which took air from outside the building, cleaned it, and discharged it outside again after it has passed through the machine, probably cleaner than when it came from the washer. This veritable throwing away of perfectly clean air appeared to be an uneconomical procedure and during the past year or more a more rational arrangement of a closed system has been used particularly for large turbo alternators. This system recirculates the same air, cooling it by passing it over water cooling pipes. The advantage of this arrangement has been recognized during the past year for application to other types of machines, it having been adopted for hydroelectric plants and substation equipment. The closed ventilating system necessarily presupposes an abundance of cooling water at low cost.

During the past year an ingenious arrangement has been devised for cooling heavy duty bearings of substation machinery where the water supply for such purposes is expensive. This scheme consists of a closed water circulating system so arranged that the water is cooled by the air used to ventilate the machine.

Although for a number of years sales campaigns have been carried on advocating the use of small fans to increase the heating capacity of radiators in very cold weather this idea has not been applied to the cooling of transformers until this year. By the use of jets of air directed over the surfaces of self-cooled transformers the convection of heat has been greatly accelerated. This development gives promise of many possibilities.

TESTING ELECTRICAL MACHINES

A renewed interest has been shown in the accurate determination of load or stray losses of rotating machines. The assumption that is made in the present A. I. E. E. Standards that the measured short circuit core loss is equal to the load loss is generally considered to be far from correct in certain types of alternators and there is a general desire for a more accurate method of determining these losses that would be suitable for application to commercial testing. A paper which was presented at the Midwinter Meeting advocated a method of test which was based on measuring the synchronous motor power input when running light under conditions of leading and lagging currents. The discussion of this paper indicated that a calorimetric method of measuring losses has been in use in one of the large factories for several years and that this method is being studied by others. The calorimetric method makes use in different ways of the observed temperature rise of the air passing through the machine. Since closed ventilating systems are being more generally used the determination of the losses by the measurement of the heat absorption by the air cooling equipment seems to offer a satisfactory method of test. These calorimetric methods do not, however, offer means of direct measurement of the so-called load losses but are more suitable for the determination of the total losses under actual load condition. This committee is desirous that suitable commercial test methods be developed for a more accurate determination of the efficiency of large synchronous machines than is now described in the A. I. E. E. Standards.

The testing of large machines on power house settings such as water wheel driven alternators often involves the measurement of losses by the deceleration method. During the past year a chronographic method has been devised for obtaining a simultaneous record of time and revolutions on a paper ribbon.

TURBO-ALTERNATORS

In this Committee's report of last year, mention was made of a 62,500-kv-a. 1200-rev. per min. turbo generator which had recently been put into operation as the largest single-shaft unit that had been built. During this year two machines of this capacity but of 1800 rev. per min. have been put into successful operation. The step up from 1200 rev. per min. to 1800 rev. per min. has been made possible by the more skillful design of the electrical parts, a better proportioning of the mechanical parts, and more extended multiple ventilation. This increase in speed makes it possible to further extend the upper limit of rating for single-shaft machines to such an extent that two 60,000-kw. units are now under construction and 75,000-kw., 80 per cent power factor generators are being considered. A machine of this rating at 1200 rev. per min. would present difficulties in manufacture because of the great weight of the rotor. Another large turbo alternator that was put into service the past year is rated 66,660 kv-a., 1500 rev. per min., 25 cycles. In France one of 60,000 kv-a., 1500 rev. per min., 50 cycles, is about ready to be put into operation. The description of this generator in a paper presented before the Institute brought out in the discussion some interesting information on the relative design practises in Europe and the United States. The French machine employed deep slots in the stator core for the dual purpose of increasing the reactance and providing axial paths for ventilation. Another feature is the much smaller ratio between saturation and impedance ampere turns than has been considered good practise in America. American practise has considered it necessary to maintain this ratio at near unity while European practise allows it to be as low as 0.5. This difference may possibly be accounted for by the difference in operating practise on the two continents. In America the apparent desire of the operators is to get the maximum output from the generator throughout its period of life, while in Europe, it is said, a generator is usually operated at slightly less than its rated capacity. Another factor has been the general practise in Europe to employ voltage regulators to care for the swings in load and supply the necessary excitation to prevent the

generators from falling out of step while in the United States operating people have insisted upon generators that may be hand regulated and which are not dependent upon automatic regulation for their stability.

It is interesting to note that designing engineers now predict the possibility of building machines having ratings of 75,000 kw., 80 per cent power factor at 1800 rev. per min., 100,000 kv-a. at 1500 rev. per min., for 50 cycles and 40,000 kv-a. at 3000 rev. per min. for 50 cycles. A 25,000-kw., 3000-rev. per min. machine has been built in Europe. It is the opinion of a leading engineer that if greater capacities than 75,000 kw. are demanded by the operating companies they will be obtained by advances in the design and materials applied to the four-pole generator rather than a return to a six-pole design. For very large units there are advantages in the cross-compound arrangement or multiple-shaft design involving two or more generators. A unit of this type having a house generator, in addition to the two main generators and with a total rating of 77,000 kw. has been completed during the past year and another of 80,000 kw. is under construction. An order has recently been placed for a two-generator unit rated at 90,000 kw. Triple shaft units with three generators of combined capacities of 160,000 kw. and 200,000 kw. are being considered.

These very high generator ratings have involved problems concerning mechanical stresses in the rotor due to centrifugal forces and deflection, insulation of the rotor windings and ventilation of the stator. Centrifugal stresses have been provided for by the development of special alloy steels. The limitations of rotor deflection in its relation to critical speed have been largely eliminated by a better knowledge of the mechanics of the problem. Whereas before this was so well understood it was believed that the rotor speed should be well below the critical speed, now the designers are concerned only that the normal speed must not approach any multiple of the first critical speed. Experience has shown that the critical speed is not dependent only on the weight and length of the rotor but that it is influenced by the type and proportions of the stator frame and bearing supports and the design of these parts offers a means of control. The very great pressures on the rotor winding insulation coupled with the expansion and contraction resulting from changes of temperature has necessitated the development of types of insulation for the end coils that will withstand these destructive conditions. In the matter of ventilation, schemes of providing a number of multiple paths have been devised to obtain the equivalent of a short core machine. In some cases as many as 28 parallel paths are provided. For the ventilation of the smaller generators fans mounted on the shafts inside the end bell housing have been used although separate motor driven fans would be more efficient. This arrangement has the advantage, however, of eliminating a separate auxiliary which if it failed to operate would cause the removal of the generator from service. The fan capacity required for the very large generators has exceeded the limit of the type that can be mounted on the rotor and separate fans or blowers are now a necessity. With well designed external blowers, having an efficiency of 65 per cent, a saving in the total losses of the machine would amount to approximately 0.1 to 0.2 per cent at rated load. On the larger machines it is often feasible by the use of external blowers to build them with smaller diameters than would be possible with fans on the rotor. Under such conditions the external blower ventilated machine may show an efficiency of from 0.3 to 0.4 of a per cent higher than the machine with fans attached to the rotor. Besides the better efficiency this arrangement affords another important advantage in that the air passes through the air coolers of a closed system after leaving the fans and before it enters the generator thus extracting the heat put into it by the fans. A material reduction in the temperature of the air entering the generator is obtained as compared with its temperature when the fans are assembled on the shaft. The closed ventilating system with fin-type radiator coolers is now being used almost universally for turbo alternators.

During the year there have been improvements in the Emmet mercury turbine with resulting higher efficiencies.

The 3000-kw. 3600-rev. per min., 20-stage turbine for operation at a steam pressure of 1200 pounds which was mentioned in our report of last year has been put into successful operation.

WATER-WHEEL DRIVEN ALTERNATORS

American hydroelectric practise still favors the vertical shaft arrangement of alternators to such an extent that about 80 per cent of the water wheel

generators are of this type and the arrangement is more or less standardized with a spider or bridge spanning the top of the armature frame for supporting the thrust bearing which carries the weight of the generator rotor and the water wheel runner. Two years ago several units were built with the thrust bearing beneath the revolving field and no bearing or superstructure above the rotor except a cover or housing. Although there seemed to be a number of advantages to be gained by this so-called umbrella type no further machines have been built 'til this year. A 6250-kv-a., 138½ rev. per. min. generator of this type is now under construction. One manufacturer is using a fabricated construction of welded steel plate to a large extent for the armature frames. The closed ventilation system has been adopted in one large water power station.

During the year a rather formidable number of large capacity alternators both horizontal and vertical shaft have been under construction or installed and the following incomplete list will serve to indicate to what extent machines of large ratings are being used.

3-37,500 kv-a.	12,000 volts,	120 rev. per min.	vertical shaft
3-18,750 kv-a.	6,600 volts,	100 rev. per min.	vertical shaft
2-29,000 kv-a.	.... volts,	300 rev. per min.	vertical shaft
2-25,000 kv-a.	13,200 volts,	450 rev. per min.	vertical shaft
2-20,000 kv-a.	11,000 volts,	200 rev. per min.	vertical shaft
1-17,000 kv-a.	6,600 volts,	375 rev. per min.	vertical shaft
1-17,500 kv-a.	6,600 volts,	100 rev. per min.	vertical shaft
2-25,000 kv-a.	6,600 volts,	90 rev. per min.	vertical shaft
2-54,000 kv-a.	12,000 volts,	187½ rev. per min.	vertical shaft
2-13,500 kv-a.	6,600 volts,	277 rev. per min.	vertical shaft
4-16,000 kv-a.	11,000 volts,	133 rev. per min.	vertical shaft
3-20,000 kv-a.	11,000 volts,	330/360 rev. per min.	vertical shaft
2-15,625 kv-a.	11,450 volts,	257 rev. per min.	vertical shaft
2-25,000 kv-a.	12,000 volts,	300 rev. per min.	vertical shaft
2-18,750 kv-a.	12,000 volts,	150 rev. per min.	vertical shaft
2-15,000 kv-a.	6,600 volts,	171 rev. per min.	vertical shaft
1-21,000 kv-a.	11,000 volts,	138½ rev. per min.	vertical shaft
1-12,000 kv-a.	12,500 volts,	128½ rev. per min.	vertical shaft
1-12,000 kv-a.	2,400 volts,	250 rev. per min.	vertical shaft
8-12,500 kv-a.	14,000 volts,	100 rev. per min.	vertical shaft
2-10,600 kv-a.	12,000 volts,	120 rev. per min.	vertical shaft
2-36,000 kv-a.	6,600 volts,	100 rev. per min.	vertical shaft
2-30,000 kv-a.	6,600 volts,	112½ rev. per min.	vertical shaft
2-10,000 kv-a.	6,600 volts,	180 rev. per min.	vertical shaft
2-33,000 kv-a.	11,000 volts,	360 rev. per min.	horizontal shaft
1-33,000 kv-a.	13,200 volts,	360 rev. per min.	horizontal shaft
2-25,000 kv-a.	11,000 volts,	450 rev. per min.	horizontal shaft
1-20,000 kv-a.	11,000 volts,	375 rev. per min.	horizontal shaft
1-14,444 kv-a.	6,600 volts,	600 rev. per min.	horizontal shaft
1-13,000 kv-a.	12,000 volts,	500 rev. per min.	horizontal shaft
1-13,125 kv-a.	4,400 volts,	225 rev. per min.	horizontal shaft

Although the 65,000-kv-a. units at Niagara Falls are still the largest machines that have been built, larger alternators have been under consideration and will probably be built in the near future. The manufacturers are prepared to build the following maximum rated water-wheel driven alternators of the vertical shaft type and designed to meet the usual run-away speed requirements:

10,000 kv-a. at 720 rev. per min.
20,000 kv-a. at 600 rev. per min.
30,000 kv-a. at 514 rev. per min.
55,000 kv-a. at 400 rev. per min.
80,000 kv-a. at 300 rev. per min.
110,000 kv-a. at 200 rev. per min.
130,000 kv-a. at 100 rev. per min.

The use of welded steel plate stator frames and the substitution of a few separate sole plates for a continuous base ring has appreciably reduced vertical shaft generator weights. Comparisons of construction and actual weights indicate that American designs are at least twenty-five per cent lower than similar European machines.

The past year has set a new record in the maximum capacity of horizontal shaft water-wheel driven generators. Two alternators rated 33,000 kv-a. at 360 rev. per min. were built in the United States for a Brazilian plant and a third was built for a California plant. In Europe a 30,000-kv-a., 500-rev. per min. horizontal shaft alternator has recently been built which has an unusual rotor construction consisting of twin rotors each with its pole pieces and windings mounted side by side on the shaft in a common armature core. This construction was adopted to conform with certain shop and transportation facilities.

The use of automatic or remote control of hydroelectric units is extending. During the past year some 9000 kv-a. units have been put into successful operation being the largest yet constructed for this type of control.

Diesel Engine Driven Alternators

There has been considerable activity during the past year in exploiting the use of Diesel engines as prime movers for stand-by plants. An installation of this type which is worthy of note consists of three 3125-kv-a, 80 per cent power-factor, 25-cycle, 125-rev. per min. units for the Panama Canal which are probably the largest generators driven by this type of engine.

Transformers

An important consideration in transformer work is the provision of means of dissipating the losses with sufficient rapidity to keep the temperature of the trans-

former within safe limits. In the past this has been accomplished by one of four methods, *viz:*

1. Air-blast, in which air is blown around and through the core and windings.

2. Self-cooled, in which the heat is transferred from the core and coils to the casing by an oil bath and then dissipated principally by radiation.

3. Water-cooled, in which the heat is removed from the oil bath by water cooling coils.

4. Oil-cooled, in which the oil bath is circulated through a cooling apparatus independent of the transformer.

A new method involving an old principle has gained much favor this year. This consists of directing jets of air upward and over the radiating surfaces thereby removing a larger part of the heat by convection than can be done by the natural circulation of air. Some very large transformers arranged for cooling by air jets have recently been completed. The rating of these oil-insulated, air-cooled distributed core type transformers is 30,000 kv-a., 220,000 volts Y, 125,000 volts Y, 10,640 volts delta at 60 cycles and 55-deg. cent. temperature rise by resistance.

The method in which the oil is cooled outside of the transformer tank is more generally used in Europe than in America. This year, however, some very large transformers arranged for this method have been built and installed in America. They are rated 20,000 kv-a., 50 cycles, 72,000-Y, 11,000-volt single-phase, and sea water is used as the cooling medium. Although air-blast transformers are not used to as great an extent as they were many years ago there is still a demand for them for installation in certain localities where the presence of large quantities of oil is considered to be a fire hazard. The largest air-blast transformer yet built was installed this year. It was rated 18,500 kv-a., 25 cycles, 11,800-3,300 volts three-phase and weighed about 43 tons.

The largest self-cooled single-phase transformers ever built were completed this year. They are rated at 20,000 kv-a, 72,450-Y, 13,800 volts, 60 cycles. Likewise the largest water-cooled transformers both in point of rating and physical size have been built this year. These are rated 28,866 kv-a., 220,000-Y, 66,000-Y, 10,750 volts, 60 cycles, single-phase. As will be noticed in the ratings of the above self-cooled and water-cooled transformers tertiary windings are being used to a large extent in large high-voltage power transformers. The tertiary windings being connected delta permit using the star connection for both primary and secondary windings. The tertiary winding also provides a means of connecting a condenser into the system for transmission line voltage regulation without using an independent transformer where the secondary voltage is too high for a condenser winding.

During the past year the largest and highest voltage transformers ever built in the British Empire were completed in Canada. These are designed for a rating of 25,000 kv-a., single-phase, 60 cycles, 154,000 volts and weigh 80 tons each. Twelve of these transformers were built on one order.

A German manufacturer has built the largest capacity transformer ever constructed. By removing the aluminum windings of a 60,000-kv-a. transformer that had been in operation for several years and substituting copper windings a three-phase transformer having a rating of 75,000 kv-a., 110,000 volts was produced. This transformer is now in successful operation.

Probably the most important development pertaining to transformer construction has been the further improvement of and extended use of transformers equipped with load ratio control or devices for changing taps without interrupting the load. Transformers of this type are being extensively used to regulate circulating currents between systems where the flow of energy is in either direction and where each system must maintain its voltage independently of the direction of the flow of energy.

One of the largest units of this latter type is a three-phase self-cooled auto-transformer rated 36,000 kv-a., 66,000 volts, 60 cycles. It is used as a tie between two 60,000-volt systems. The taps are arranged to give 10 per cent buck and 10 per cent boost in nine steps. The total weight of this transformer with operating mechanism and circuit breakers is about 73 tons.

The electrical circuit of this unit is novel in that double transformation is employed to secure voltage control. Electrically, the unit consists of two distinct transformers each provided with a high-voltage and low-voltage winding. The high-voltage windings of each transformer are connected to the 66,000-volt line, one being connected in shunt to the line and the other in series to the line. The shunt transformer contains the necessary taps and ratio adjusters by means of which fractions of the low voltage winding on the shunt transformer can be connected to the low-voltage winding on the series transformer. By varying the taps the desired amounts of voltage either bucking or boosting can be inserted in the high-voltage line through the series transformer. By thus placing ratio adjusters in a separate low-voltage circuit the switching apparatus is protected from abnormal voltages which may arise in the high-voltage lines.

It sometimes becomes desirable for the sake of greater insurance against interruption of service to separate the regulating function into a separate transformer. An interesting example of this consists of banks of three single-phase, self-cooled, power transformers rated 20,000 kv-a., 12,600-13,800 volts, 60 cycles, a three-phase, self-cooled, regulating transformer of 60,000 kv-a. capacity.

Transformers having arrangements for tap changing under load are also being extensively used for electric furnace work.

The extension of the idea of rural electrification has opened up a new field of design in small distribution

transformers for very high voltages. Some 100-kv-a., 110,000-volt transformers have recently been built for this purpose.

During the past year the largest potential transformers were built for use in America. These were designed for use between line and neutral of a 144,000-volt system. They have only one high-voltage bushing, the neutral being grounded to the cover.

The development of successful high-voltage transformers is assisted greatly by accurate knowledge of very high-voltage phenomena which can be obtained only by experimentation at voltages much higher than the actual transformer potentials. During the year a study has been made of transformer and other high-voltage insulation with a 2,000,000-volt lightning generator for the purpose of obtaining practical information in designing apparatus to resist the effects of voltages induced in transmission lines by lightning. High-voltage testing sets to provide voltages as high as 2,100,000 volts have been constructed. These consist of 350,000-volt transformers connected in series or in chains, each succeeding unit being insulated from ground by supporting it on insulating cylinders.

Improvements have been made in the temperature-indicating devices that are being used more generally to check the actual operating conditions of service transformers. A model has been produced which is suitable for use with subway transformers.

Of special interest to radio telephone engineers and enthusiasts is the development of a transformer for use with the ignition systems of oil heaters which successfully eliminates radio interference trouble, a serious objection to electric ignition in these devices heretofore. This transformer is provided with an internal magnetic blocking filter as well as low-voltage and high-voltage filters. During the past year the largest high-voltage oil-immersed reactors were constructed that have ever been built. They were rated 1300 kv-a., 3000 volts for operation on a 73,000-volt, 60-cycle circuit. A distinctive feature of these reactors is that they were provided with shielding coils to prevent the stray magnetic field entering the steel tank and setting up additional losses. Air-cooled reactors have presented a serious difficulty due to the fact that they would flash over when a failure occurred on the circuit in which it is connected if any conducting material were lodged between the turns. An investigation has been carried out to determine a suitable insulation for the conductor of this type of reactor which indicates that a heavy asbestos covering will prevent flashovers from this cause.

A new transformer connection having 100 per cent apparatus economy for transformation from two-phase to three-phase, or vice versa, has been devised which has been described in a paper presented to the Institute.

Some very large single-phase transformers that are quite novel in certain respects have been built recently in Europe for 16⅔-cycle railway work. They have three windings so arranged that power may be supplied from any one winding to either one or both of the other two. One of the two cores carries a 132,000-volt winding, the other carries a 66,000-volt winding and a 15,000-volt winding is divided into four parallel sections on both cores. It is stated that with this arrangement the bus bars and oil switches are not necessary on the 15,000-volt side. These transformers are rated 11,000 kv-a. and the total weight including oil is 117 tons.

A new protective device for large transformers has been developed in Germany which is called the Buchholz Relay. The operation of this relay is based on the fact that practically any trouble in an oil-insulated transformer will create gases which rise to the surface of the oil. A small amount of gas will cause the relay to operate. This relay will detect incipient troubles that will not actuate a current operated device and will disconnect the transformer before great damage is done. This relay can be used where the differential relay scheme cannot be applied.

D-C. Machines

A new record has been set in direct-current motor capacity by the construction of an 8000-h. p., 40-rev. per min., single-armature blooming mill motor. Several 7000-h. p. reversing mill motors have been built and the power for the first edging rolls to be equipped with electric drive is supplied by two motors of 2000 h. p. each. The simplicity and flexibility of speed control of

direct-current motors make them very desirable for variable speed drives and there has been considerable activity in the construction of large motors for steel mill work.

A new type of armature winding has been developed and applied to many commercial machines. This winding, because of the shape of the coils, is called "Frogleg" and is a combination of a wave winding and a multiple winding arranged so that the armature is cross-connected by the wave winding and all cross connections at the commutator and at the back of the armature are eliminated. This type of winding provides complete cross connection which is very desirable for good commutation. The winding is arranged so that each slot contains four bars, two of which are in the wave winding circuit and two in the multiple winding circuit, and each commutator bar is connected to both circuits.

At a recent exhibition in Europe a direct-current generator rated at 12,000 amperes and 5 volts was shown.

The use of multiplex windings has, in general, been avoided due to the failure of these types to properly commutate in certain instances and to the uncertainty of satisfactory results. A paper has been presented calling attention to certain rules that must be observed when multiplex windings are used.

Frequency Changer Sets

During the year a 40,000-kw. frequency changer set of the cascade induction motor type has been built and put into service and two sets of this capacity having both machines of the salient pole type are under construction, one of which is arranged with a spring support for the 25-cycle generator so that it may be used for single-phase power. A 7500-kv-a. set for converting from 60-cycles three-phase to 25-cycles single-phase is being built with the stator of the single-phase generator spring supported. The purpose of the spring support is to minimize the effect of the vibration incident to single-phase operation at low frequencies.

An automatic control equipment has been arranged to remove the field excitation of the motor and reduce that of the generator of a frequency changer set when a disturbance occurs on the motor circuit and again to restore the excitation when the line voltage is normal. This type of control called for a special design of the pole face winding to enable the motor to resynchronize while the generator is carrying part load at the reduced voltage. The benefit of this arrangement has been a greatly improved service due to a material reduction in the length of the interruptions.

Synchronous Condensers

Considerable advancement has been made recently in the design of synchronous condensers toward the reduction of losses. In sizes above 5000 kv-a., the losses are now as low as from 1.75 per cent to 2 per cent. The extension of high-tension distribution systems and higher transmission voltages has expanded the field of line voltage regulation by the use of synchronous condensers very rapidly. The largest condenser ever built, rated at 40,000-kv-a., 600 rev. per min., was recently put into operation in connection with a 220-kv. transmission line. The important consideration of keeping the losses down to a minimum has resulted in a strong tendency toward higher speeds. A considerable number of machines of 25,000 kv-a. to 40,000 kv-a. at 600 rev. per min. and of 15,000 kv-a. at 720 rev. per min. have been built. The disadvantage of the noise at these high speeds has been overcome largely by a totally enclosed construction.

An interesting development in the automatic control of synchronous condensers for line voltage regulation has been an installation of a 1000-kv-a. condenser provided with a voltage regulator arranged to start and stop on voltage indication. The condenser is at the end of a long transmission line and remains connected to the line through the starting tap in case of complete failure of power, thus providing a reactance for line protection when power is restored.

Synchronous Motors

The past year has been marked by a further extended use of synchronous motors for many applications where induction motors have formerly been considered necessary. This extended use has been reflected in the development of complete lines of general purpose synchronous motors. The construction of a 9000-h. p., 6600-volt motor is of particular interest because of its application to the main roll of a steel mill and because it is the largest continuous rated motor of any type to be applied to industrial purposes. About 1½ per cent higher efficiency and the absence of about 4000 reactive kv-a. are the principal advantages obtained over a corresponding induction motor.

Another interesting development is a single-phase synchronous motor as part of a motor-generator set for use on heavy duty electric locomotives to supply direct current power to the main motors of the locomotives. These motors are rated 1200 kv-a.,

2300-volt, 25-cycle, single-phase for the freight locomotives, and 500 kv-a. for the smaller switching engines. These sets are brought up to about 80 per cent of synchronous speed by a starting motor of the repulsion type and then the motor is connected to the line at full voltage after which it quickly comes up to full speed and the excitation is automatically applied by a relay actuated by the current induced in the field during the starting period.

Induction Motors

No outstanding developments in the electrical design of general purpose induction motors have been brought out during the past year but the attention of designing engineers has been directed more particularly to the improvement of constructional features as relating to mechanical design and economical manufacture. A number of manufacturers have developed complete new lines with improved mechanical features.

The relative merits of sleeve and ball or roller bearings is a subject over which there is considerable discussion and difference of opinion. While a few manufacturers feature ball or roller bearings exclusively, the larger firms are prepared to supply either type according to the preference of the purchaser. New lines having tapered roller bearings have been developed which have overcome the assembly difficulties that previously made this type of bearing appear to be impractical for this application. General improvements have been made in the construction of the sleeve type of bearings to overcome the oil throwing and to exclude dirt and dust from entering the bearing which were objectionable features of the older design.

One manufacturer has adopted a fabricated construction of the mechanical parts of induction motors to the exclusion of cast parts except for the end bells. Another is using pressed steel end frames and riveted feet for moderate and small size motors. The motor manufacturers have in general retained the conventional casting construction for standard lines. General purpose motors having cast steel parts have been featured by one manufacturer while another has used the welded construction for large special motors.

Improvements in the power factor characteristics of induction motors have been accomplished by the adoption of more precise manufacturing methods. For instance, a grinding process has been adopted for finishing the stator and rotor cores of small machines to obtain uniformity of air gap. The use of larger bearings and shafts has permitted reductions of the air gaps resulting in better power factor. However, there is a strong conviction among designing engineers that better practise in application engineering presents the greatest possibilities for the improvement of power factor conditions in general power distribution systems. It is particularly important to avoid over-motoring, *i. e.*, installing motors of needlessly large capacity and operating them at low loads and consequently low power factor.

The ever extending use of electric power is presenting new and more severe conditions affecting the insulation of motor windings. Improvements in insulating materials and processes are being continually sought for the purpose of minimizing the destructive effects of dust, vibration, acid and alkaline vapors, and moisture. Form wound coils which are completely insulated before they are assembled in the slots present the least difficulties in that the interior of the coils can be completely filled with varnishes or compounds, but the so-called random wound coils in which the wires are not bonded together have presented a more difficult problem. A recent improvement in this type of winding has been obtained by encasing the complete end windings outside of the slots in a plastic insulating material.

During the year considerable attention has been given to theoretical studies of the performance characteristics of the synchronous induction motor and the compensated induction motor which combine the power factor characteristics of the synchronous motor with the starting torque characteristics of the wound rotor induction motor. For a number of years a type of synchronous induction motor arranged to receive its excitation from an external source has been in general use in Europe.

As mentioned in this committee's report of last year two new types of synchronous self-excited, induction motors have been developed in America. Another type of compensated motor has been developed this year in Europe which uses the Leblanc principle with one rotor having separate windings in separate slots. Although the use of the self-excited synchronous induction motor is being extended in America it has not reached anywhere near the proportions of the use of the separately-excited motor in Europe. American practise accepts the ordinary induction motor for general use supplemented by a relatively few synchronous machines for the purpose of maintaining good power factor conditions.

A European manufacturer is building a complete line of induction motors up to 225 h.p. with centrifugal-operated starters which have the same efficiency and power factor characteristics as the usual wound rotor type. This arrangement offers greater simplicity of starting than the ordinary manually operated compensator or controller. Compared with this the general practise in America has been to avoid the use of centrifugal devices and built-in resistances in polyphase motors. A recent European development has been a line of water cooled, totally enclosed motors primarily for pump drives. These motors are capable of being rated up to 70 per cent of the rating of the open type frame of the same size.

An interesting new development has been the design of a high-resistance squirrel-cage motor used largely for driving sugar centrifugal hydro extractors, etc.

The principal part of the load on this machine being the starting and stopping of a load of high inertia, it follows that the principal part of the losses in the motor are in the squirrel cage winding. The rotor of this motor has been designed with a high resistance section to the squirrel-cage winding which is built in the form of a fan to effectively dissipate the heat developed in the squirrel cage without communicating the heat to the rest of the motor.

A notable step in large size induction motors has been the building of a blooming mill motor having a continuous rating of 8000 h. p. at 13,200 volts. This is the largest continuous rating at the highest voltage yet obtained in induction motors.

Full voltage starting of induction motors is being urged by some engineers who claim for it greater efficiency, greater simplicity and lower cost, but there is a marked reluctance to abandon the time honored use of auto-transformers for reduced voltage starting. The so-called double squirrel-cage motors or those having high reactance rotor windings for full voltage starting or applications requiring high starting torque seem to be growing in popularity especially for high-speed ratings where the inherent reactance of the standard construction is low.

High-Frequency Machines

During the past year a new development in high-frequency alternators has resulted from relatively new developments in the use of high-frequency power. The successful operation of air-core induction furnaces for melting copper, brass and nickel, and silver alloys has called for the development of generators suitable for supplying power at about 480 cycles for one type of furnace and at about 2000 cycles for another type. Current of 2000 cycles is also used for heating long objects of small sections such as boiler tubes. Generators for these purposes have been built in capacities up to 600 kw., single-phase, 480 cycles, and 150 kw., single-phase, 2000 cycles.. A further application of high-frequency power has been to obtan very high motor speeds for wood cutting and grinding operations and generators for three-phase power up to 420 cycles have been built for this purpose. These generators have been of the standard salient pole type, which is preferred to the inductor type because of the better characteristics. The high speeds and large number of poles has necessitated some special types of windings and mechanical details. A consideration of the fact that with a limiting peripheral velocity of 15,000 feet per minute the pole pitch of a 2000-cycle alternator is only ¾ inch will give some idea of the limitations of the field structure of such an alternator. The use of two-pole induction motors on frequencies of from 300 cycles to 420 cycles producing speeds of 18,000 rev. per min. to 25,000 rev. per min. has presented problems in motor construction more of the mechanical nature than of an electrical nature. The present limitation of speed is due to bearing troubles but the problem of the lubrication of high speed bearings is being studied with the hope that higher speeds can be used successfully if they are found desirable.

A recent European development for obtaining high motor speeds for wood working machinery consists of a combination motor having two stators and two rotors which are concentric. This motor develops a speed of 6000 rev. per min. on 50-cycle current. American practise has used the simpler high frequency motor supplied with power from frequency changer sets.

Synchronous Converters

Conditions in England have led to a careful study and development of motor-converters and apparent success has been obtained with a larger output per pole than has been obtained with d-c. machines in America. Ameri-

can practise has pinned its faith to the conventional six-phase synchronous converter. The largest capacity converter set that has been installed for heavy duty, 1500-volt, d-c. traction service was built during the past year and consists of two 1500-kw. rotary converters connected in series. Limitation of space available for the installation of a 4200-kw. synchronous converter led to a rather unique arrangement. It was desired that the transformer should be set on the base of the converter at the collector end. In order to make use of the space on both sides of the shaft, the transformer was split into two units each of half the total capacity and each connected six-phase and the converter was built with twelve collector rings for twelve-phase operation, taking advantage of higher efficiency, smaller space and lower cost. This is the largest twelve-phase converter of which we have knowledge.

An ingenious arrangement for obtaining a stepless voltage control of a direct-current power supply for crane motor operation has been devised by a European manufacturer which consists of a small three-phase synchronous converter which is direct connected to a self starting synchronous motor or booster. The stator of the booster is arranged so that it can be shifted angularly thereby varying the direct-current voltage of the converter from zero to plus or minus full voltage. The complete outfit is of small enough dimensions to be mounted in the crane cab.

Induction Disk Phonograph Motor

Further applications of induction disk motors have recently been made to low-power, low-speed equipment. These motors operate under the same principles as used in the customary induction-type alternating-current watthour-meter. The rotor consists of a conductive disk, through which a shifting flux is produced by one or more split phase electromagnetic elements. Eddy currents are generated in the disk and the reaction between the eddy currents and the flux produces the driving torque.

The chief applications of induction disk motors heretofore have been as timing devices in demand meters, time switches, etc. However, a larger motor has now been perfected for phonograph drive and has been adopted by two of the most prominent phonograph producers. The chief advantages of this motor are silence, constant speed, lack of vibration and reliability. The rotor runs on a vertical shaft, the upper end of which also carries the phonograph turn table. No speed reducing gears are therefore necessary, the rotor turning at slow speed and driving the turn table directly. The motor has high starting torque, giving it rapid acceleration. The speed is controlled by a very sensitive fly-ball governor, operating through friction. The normal speed is 78 to 80 revolutions per minute, at which a torque of 6 inch ounces is produced, this being sufficient to drive any standard phonograph. The input to the motor is approximately 35 watts.

An important advantage of this electric phonograph motor over the spring motor lies in the fact that the former supplies a constant driving torque regardless of the length of time it is operated, whereas the spring motor delivers a varying torque. The torque of the spring motor starts at a rather high value just after it has been fully wound and tapers down to a low value as the spring unwinds.

The induction disk motor is desirable, of course, only for low power applications having a low efficiency. It is very reliable and silent, however, owing to its relatively slow speed and simple construction.

Induction Voltage Regulators

A new development in connection with induction voltage regulators has been the combination of a series transformer and a transfer switch with the regulator and so arranged that the polarity of the series transformer may be reversed thereby doubling the range of the regulator. The cycle of operation of the combination produces the same results as would be obtained by a regulator of twice the capacity. The switch is geared to the regulator which may be automatically operated. An outdoor type of regulator has been developed with all the auxiliaries including current and potential transformers mounted within the auxiliary casing. Induction regulators have been developed for use on 12,000-volt single-phase circuits. The noise of single-phase regulators has been materially reduced by the use of a cushion support for the regulator in its tank and a similar cushion between stator and rotor. An indicator has been developed to show the boosting or lowering position of the regulator rotor.

Mercury-Arc Rectifier

During the past year the mercury-arc rectifier has been further developed and notable improvements have been made particularly with regard to the automatic upkeep of the vacuum and to simplifying the control and auxiliary apparatus. This piece of apparatus would appear to approach the ideal for the rectification of alternating current in that the function is performed without transforming the energy into magnetic and mechanical energy with the attendant losses. The loss affecting the efficiency of the rectifier is the arc drop within the tank and since the arc drop is approximately constant the rectifier does not show as high efficiency at rated load as does the rotary converter for large low voltage capacities. For heavy duty traction purposes involving voltages above 600 volts

the rectifier has better efficiency characteristics. American manufacturers are now offering rectifier equipments for railway substations and industrial power uses that may operate in parallel with rotary converter or motor generator equipments and arranged for complete automatic operation. Rectifiers are usually supplied with a slightly dropping characteristic, which may be adjusted to match the characteristics of shunt wound rotary converters operating in parallel. Rectifiers may also be compounded in order to obtain voltage control; however, it must be appreciated that this control will slightly lower the over-all efficiency and power factor of the rectifier unit. Equipment has been developed to include the application of automatic voltage regulators for maintaining constant d-c. voltages. A peculiar advantage of the rectifier over other types of converters from a commercial point of view is that the rating of a unit is independent of the frequency of the alternating current and within certain limits a given rectifier is suitable for operation at various voltages, the kilowatt capacity being greater the greater the d-c. voltage. While rectifiers have been extensively used in Europe for more than one decade, there are only two commercial installations in America which have been in commercial service for more than one year. A few more were added during the past year, and a large number of equipments are on the books of American manufacturers and will go into service this year.

The voltage limitations of the rectifier are much higher than those of synchronous converters and motor-generator sets, for they are built in capacities as large as 3000 kw. at 4000 volts d-c. One 4000-volt plant has been in successful operation for more than two years on a standard gage railroad in Europe. These capacities are characterized by very high efficiencies. Since the loss is due only to the resistance drop of the arc the efficiency is inherently higher for the higher voltage ratings. Other advantages which have been claimed are that there is no synchronizing operation and there are no moving parts. The absence of noise and vibration makes the rectifier peculiarly desirable for substations in congested and residential districts where quiet operation is necessary. The successful operation of a rectifier depends upon maintaining almost a perfect vacuum and equipment is available which will accomplish this automatically. The operation of this equipment is based upon the principal that the transfer of heat from one body to another is accomplished by radiation and conduction but the conduction is dependent upon the gas pressure and is zero in an absolute vacuum. This device is called a hot wire vacuum gage.

The operation of rectifiers of this type is liable to be interrupted by an occasional arc-back which is a short-circuit between anodes and occurs when one or more anodes function temporarily as a cathode. Since this occurrence causes no damage to the equipment except in very rare cases, the rectifiers may immediately be restarted by reclosing the breakers either manually or automatically. The cause of arcing back is being studied and it is hoped that this difficulty will be overcome.

STEAM POWER VS. WATER POWER

Is steam power to outdistance water power for generating electric current in the Pacific Coast country where "white coal" is king? This tendency is noted by the Journal of Electricity in an editorial declaring that cheapness of oil fuel and 300-per cent advances in the efficiencies of steam generating machinery during the past decade indicate that steam power may prove the more economical even in the water-powered state of California. Only one-third of the electric energy used in the state is generated by steam today, while hydroelectric plants produce the balance but engineers are prophesying the ratio may soon be reversed.

"A majority of the hydro power sites have been or are being developed," says the editorial, setting forth the facts of the case. "Efficiencies of 85 to 90 per cent of the theoretical have been obtained in waterwheels and there is little opportunity for improvement here. A cycle of comparatively dry years has placed added emphasis on steam plants.

"Many of the western states abound in low-grade coal which can be utilized either in pulverized form, as has been done successfully in Washington and Colorado, or can be subjected to low temperature distillation and burned in the form of coke and gas. Even California has extensive fields of lignite, and transportation facilities are such that cheap coal can be brought from Utah, Arizona, New Mexico or Washington. Whether steam will supplant hydro in supremacy is a debatable subject but certainly conditions point to a decided swing of the pendulum toward steam."

Notes on the Vibration of Transmission-Line Conductors

BY THEODORE VARNEY[1]

Associate, A. I. E. E.

Synopsis.—*This paper describes tests made with a graphic recorder to show the vibration of transmission-line conductors under various conditions of wind velocity, conductor tension and span length. The method of taking the records is discussed. Formulas are given for determining the velocity of propagation of transverse waves along a conductor, the wave length of a vibration, and the frequency of vibrations caused by "eddies" formed at a conductor subjected to air currents.*

If a wire is suspended freely between supports and is struck near one of the supports, a wave will run along the wire to the other support, be reflected and return to the starting point. If the supports are rigid, that is, possessed of infinite mass, the wave will be entirely reflected and it will pass back and forth until the viscosity of the wire damps out the wave. With a decrease in the mass of the support, the amount of the wave energy reflected is lessened. Part of the energy passes into the support, either storing energy therein to be given back to the latter if the support is elastic, or becoming dissipated by the viscosity of the support.

Assuming that the tension in the wire is constant, the velocity of propagation of the transverse wave is:

$$v = \sqrt{\frac{P}{m}} = \sqrt{\frac{P\,g}{w}} \qquad (1)$$

When

v = Velocity in feet per second
P = Total tension in the wire
m = Mass per ft. of wire
w = Weight per ft. of wire in pounds
g = Acceleration due to gravity

The time required for the wave to travel twice the length of the span is the fundamental time period. If at the instant the first impulse reaches the starting point the wire is struck again, the vibration will be sustained. If at the instant the impulse reaches the second support the cable is struck again, the two crests meet at the center, producing a node. If the frequency of the exciting force is increased, the span breaks up into a series of nodes and loops. If resonance occurs, there must be a whole number of loops between supports, provided the mass of the wire is uniform.

The velocity remaining the same, the product of wave length and frequency is a constant and is equal to the velocity; that is,

$$l\,f = v \qquad (2)$$

Where

l = Twice the distance between nodes
f = Frequency in cycles per second

In cases where resonant vibration of conductors has been observed, it was traceable usually to the wind blowing across the line and always at low velocities. A strong wind broke up the resonant conditions and merely swayed the span as a whole. The vibrations were in a vertical plane. Resonance appeared more frequently in the early morning or near sundown. Resonance also occurred over a wide range of cable tensions.

Resonance in a transmission cable is a very elusive thing; it begins without warning and ceases abruptly, and, while the conditions at the moment as regards temperature, wind velocity and direction may be noted, it is impossible to maintain or reproduce them at will.

It was at first thought that a span vibrating with fixed nodes and loops would not be affected by moving the point of support to the first node. If this were true, then the behavior of a single loop could be investigated on a small scale, experimentally, and would afford means of observing the behavior of a full sized span. Accordingly, an attempt was made with several sizes of stranded cables to produce resonant vibration by mounting the cable transversely in an aviation wind tunnel. The tunnel used was 8 ft. square and the wind could be varied from zero to 75 mi. per hour. The cables were supported at the sides of the tunnel and the tension in the cable was varied over a wide range.

No resonant vibrations could be produced. The cables vibrated rapidly with a very small amplitude, not over one one-hundredth or two one-hundredths of an inch. These small vibrations were noted by means of a reflecting mirror and a stroboscope and were found to agree fairly well with the eddy frequency.

The meaning of the expression "eddy frequency" will be explained later.

The probable reason why resonance and considerable amplitudes could not be obtained in the wind tunnel is that it is difficult to maintain constant wind velocities over the whole length of span. Moreover, upon further thought, it is more difficult to maintain approximately resonant conditions over a short span than it is over a long one. If, to assume an example, the wind velocity were adjusted so as to produce one loop in an 8-ft. span, it would require a change in wind velocity of 100 per cent to create the next larger whole number of loops, that is two, in the span. Any intermediate value of wind velocity would not produce resonance. If, on the other hand, the span were 80 ft., a 10 per cent change

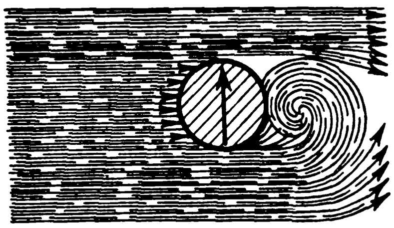
1. Aluminum Company of America, Pittsburgh, Pa.

Presented at the Regional Meeting of District No. 1 of the A. I. E. E., Niagara Falls, N. Y., May 26-28, 1926.

in velocity would be necessary to produce either nine or eleven loops in the span, while in a span 800 ft. long, only 1 per cent change would be necessary to produce 99 or 101 loops in the span.

In actual long spans of transmission lines, the nodes have been observed to shift back and forth in position with the slight changes in wind velocity, the vibrations, however, persisting with considerable amplitude for long periods of time.

In 1921 an investigation made by E. F. Relf and E.



Eddy Formation Produced by Wind Blowing on a Wire

Ower and covered by a report to the British Aeronautical Research Committee, showed that the singing note produced by wires moving rapidly through the air corresponded with the periodic eddies produced behind the wire.

When a fluid medium, such as air or water, flows past an obstruction in its path, eddies are produced behind the obstruction. If the obstruction is of symmetrical cross section such as a circle, the behavior of the eddies formed will be similar upon each side of the obstruction. As the fluid flows past the obstruction, the friction on the two sides is not exactly the same at any particular instant and this tends to slightly lower the velocity of the fluid passing on one side. The fluid on the other side, continuing in its normal velocity, creates a slight difference of pressure back of the obstruction, the lower pressure area being on the side where the higher velocity exists. This causes a flow of the fluid from the opposite side to fill this rarified area, and the action of the fluid takes the form of swirls or eddies. As this rarified area is restored to normal density by the inflow of the eddy, the velocity on that side of the wire is reduced and the inrush of the eddy accelerates the motion of the fluid on the other side and presently the eddy ceases on the first side and begins on the other, thereby repeating the cycle of events.

The result of this alternating-eddy formation is to produce an alternating force on the obstruction in a plane at right angles to the flow of the fluid. In aircraft work, the obvious means to prevent the formation of these eddies is to "stream-line" the section of the obstruction, thereby allowing the air to flow down both sides and join at the rear edge of the section without the formation of these eddies. The figure shown herewith illustrates this eddy phenomenon.

Experiments in both air and water were carried out from which the truth of the following general expression was established:

$$f = \frac{V}{D} \text{ function} \left(\frac{V\,D}{e} \right) \qquad (3)$$

Where

f = Frequency in cycles per sec.

V = Velocity of the medium with respect to the cylindrical wire

D = Diameter of the wire

e = Coefficient depending upon the medium, being 0.000159 for air and 0.0000122 for water

Further investigations gave the following data;

When

$$\frac{V\,D}{e} = 100, \text{ function} \left(\frac{V\,D}{e} \right) \text{ equals } 0.125$$

$$\frac{V\,D}{e} = 150, \text{ function} \left(\frac{V\,D}{e} \right) \text{ equals } 0.150$$

$$\frac{V\,D}{e} = 300, \text{ function} \left(\frac{V\,D}{e} \right) \text{ equals } 0.172$$

$$\frac{V\,D}{e} = 600, \text{ function} \left(\frac{V\,D}{e} \right) \text{ equals } 0.185$$

When

$\frac{V\,D}{e}$ is greater than 600, function $\left(\frac{V\,D}{e} \right)$ equals 0.185

It will be noticed from the foregoing that function $\left(\frac{V\,D}{e} \right)$ is a constant for values of $\frac{V\,D}{e}$ of 600 or greater. For a wind velocity of one mile per hour, the minimum value of D would be 0.78 in. For two miles per hour the minimum value of D would be 0.39 in. Therefore for usual transmission line conditions, a constant value for the function $\left(\frac{V\,D}{e} \right)$ can be used. Curves of frequency plotted against wind velocity become, therefore, a series of straight lines—one for each diameter of conductor.

As a check upon the application of this theory, the following results tabulated from a long series of painstaking observations upon a certain transmission line are of interest. The cable in this case was 1 in. diameter, weighing 0.858 lb. per ft. and was supported upon steel towers.

The accompanying charts were obtained by attaching one end of a string to a transmission wire and the other end to a light wooden block arranged to slide in a slot in a vertical board which was fastened to a board resting on the ground. The lower end of this block had attached to it a light spring which served to keep the string taut and yet permitted the block, with the pencil attached, to move up and down in response to the

vibrations of the transmission-line wire. The spring was attached as nearly as possible at the middle point of the first node from the insulator clamp.

A wooden slide with a strip of paper attached to it was then moved in a direction at right angles to the movement of the pencil and was timed with a stop-watch. The device was crude but the charts afford a means of determining quite accurately the total number of vibrations produced in a certain time.

In the cases described herein the cable was quite large and the vibration had sufficient force so that the string could be pulled quite taut without damping the vibrations. This prevented, to a considerable extent, interference due to the fluttering of the string by the wind.

In other cases where the wire was smaller and the fluttering of the string interfered with proper results, a temporary platform was erected on the tower and by cutting off the current on the line, some charts have been obtained by attaching a pencil directly to the wire. The first described method has the advantage that it can be used on a live line and charts can be made on short notice, whenever the wind conditions are observed to be favorable, without taking time to cut the power off the line and arranging for a series of observations. However, as noted, it is very often difficult to

obtain satisfactory results by this means in the case of small line wire. The amplitudes of the vibrations are obtained by measuring the charts directly.

In the tabulations given herewith, the figures in column 1 refer to the number of the charts as appearing on the reproduction of the charts themselves. The second column gives the length of span where these particular charts and observations were made. In this case, the supports were practically level. It will be noted that the observations are made upon two-span lengths. The third column gives the total tension in pounds in the span at the time of the observations. These tensions were calculated from the observed sags. The fourth column gives the theoretical velocity of propagation of transverse waves in the cable as described in equation (**1**).

Column 5 gives the wind velocity in miles per hour as noted by a portable anemometer used during the experiments. Column 6 gives the theoretical eddy frequency calculated from the size of wire and observed wind velocity, using equation (**3**). In equation (**3**) the values of V and D must be in the same units; that is, V is feet per second and D is diameter in feet of the conductor. Also, these units might be used in terms of inches per second and inches of diameter.

Column 7 gives the frequency in cycles per second as taken directly from the charts. Column 8 gives the amplitude also measured directly from the chart. Column 9 is the calculated loop length using equation (**2**). The values of V in this equation are taken from column four and the values of F are taken from column 7. The values in column 9 obtained by this means are, therefore, theoretical but they check with a fair degree of accuracy with the actual observed distances between nodes at the time of the observations.

On account of the variable character of the wind under most conditions, however, these node points were observed to shift constantly back and forth. Usually, however, they corresponded to values sometimes smaller and sometimes greater than the loop length given in column 9. It is assumed, therefore, that the theoretical values given in column 9 are fair assumptions.

Chart 8 is particularly interesting because of the absence of "beats" and the exact agreement between the eddy and observed frequency. This is interpreted as indicating a practically uniform wind velocity throughout the entire span. It is likely also that the time period of oscillation of the tower supports acts to amplify or damp the line vibration.

A device at the support which has a period corresponding to a certain proportion of the natural period of the conductor will act as a damper. Such a damper having a period of about seven cycles per second would probably be effective in greatly reducing the amplitude of vibrations in the conductor throughout the range of wind velocities noted in the case described herein.

It is reported that the device recently described in the technical press[2] by Mr. G. H. Stockbridge, of Los Angeles, California, has been found effective. Further investigations on transmission lines in service are at present going on.

The writer is indebted for various courtesies and assistance in obtaining the data described in these notes from Capt. Wm. McEntee and Dr. A. F. Zahm of the United States Navy Yard, Washington, D. C.; Mr. H. A. Barre and Mr. H. Michener of the Southern California Edison Co., Los Angeles, Calif; Mr. A. E. Silver, Electrical Engineer, Electric Bond & Share Company, New York and to Messrs. M. E. Noyes, J. P. King, Walter Hays and C. B. Owen, Aluminum Company of America.

HYDROELECTRIC DEVELOPMENT IN FRANCE RETARDED

France has water-power resources which, under satisfactory conditions, are capable of producing the electric energy necessary for its economic advancement. A serious effort has been made to utilize these valuable natural resources, but unfavorable conditions for some years have impeded such efforts, and recent statistics on electric development show a marked decrease as compared with expected results. Although construction works begun during or subsequent to 1916 have been steadily continued and improvements have been made to the installations already in use, the carrying out of the greater part of new projects, for which plans were completed at the beginning of 1924, have been indefinitely postponed.

The average amount of current supplied by French hydroelectric plants during the period 1922 to 1924, inclusive, increased from 658,560 to 1,263,260 kilowatts, but the increase registered for 1925 was only about 50,000 kilowatts, and even this greatly slackened rate will probably not be maintained in 1926. This stagnation is not caused by decreased demand for additional current, for consumption of electric current steadily increases. During the past year there has been a tendency to meet this demand by the enlarging or erection of fuel power plants rather than by the installation of hydroelectric plants. The result is that three-fourths of the electric current furnished to consumers in France by the entire system of electric distributing stations is supplied by fuel power plants.

Lack of finance is the chief cause of this condition. The Government has made a careful survey of the electric power resources and has reached the conclusion that systematic construction and installation should be inaugurated and future development promoted. Special legislation and financial enactments are now pending which are intended to rectify the present situation by providing sources of revenue and foundations for loans.

Some Notes on Electricity Transmission and Distribution Practise in Europe with Comments on High-Tension Substations and Switchgear

BY G. F. CHELLIS[1]

Member, A. I. E. E.

Synopsis.—*This paper describes some of the more recent overhead and underground electricity transmission developments in Europe and is intended to convey a general idea of the status of that art in some of the European countries.*

No attempt has been made to include all the recent high-tension lines in the countries touched upon, but those included are typical of the work being done and the voltages in use.

A most interesting part of the paper is a summary and analysis of the recent report of the Weir Commission of England recommending a policy with regard to superpower development in that country. This report covers a program extending to 1940 and proposes a plan of interconnection and base-load plant construction intended to tie together practically all parts of England.

* * * * *

GENERAL

A CONSIDERABLE amount of electrical plant construction has been going on in Europe during the last five years to meet increases in power demand, resulting principally from industrial growth.

Water-power has been developed wherever possible, but regardless of high fuel cost and uncertainty as to fuel supply, steam plants have been necessary in certain areas.

Recent statistics indicate that the electricity consumption per capita in some of the European countries is higher than in the United States, but such statistics are confusing and do not present a true picture of electrical progress, except where industrial and domestic consumption are separately shown. This point is clearly brought out by considering the total unit consumption in certain mining and industrial communities where it amounts to 50,000 watts or more per capita, but with relatively low domestic consumption.

A good deal of work must be done to educate the public to a greater use of electrical energy, and growth of domestic load in Europe should, therefore, be slower than in American communities which are being energetically exploited.

Although there are wide variations in climatic and topographical conditions, government regulations, and engineering points of view in Europe, there seems to have been produced in the different countries, types of line construction well suited to local conditions.

There is considerable diversity in the design of transmission line supports which, in general, are somewhat more flexible than the usual American designs; while spans are shorter, with relatively higher safety factors in conductors.

SWEDEN

As the distances over which power has to be transmitted in the European countries are relatively shorter, such extensive transmission line networks as those which have been developed in the United States, and Canada, are not found.

The Swedish State Lines, planned by the Royal Board of Water Falls, are perhaps an exception to this general statement, as these lines form the nucleus of an extensive future superpower system designed to work at

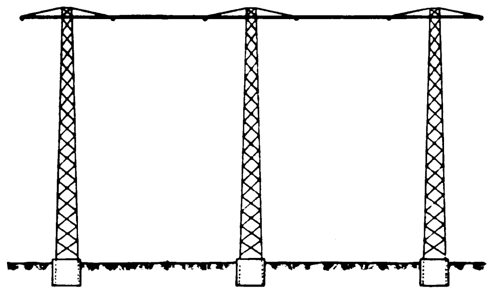

FIG. 1—TYPE OF STANDARD STEEL SUPPORT FOR TWO 200-KV., THREE-PHASE CIRCUITS

(TROLLHATTAN-VASTERAS LINE OF SWEDISH STATE POWER SYSTEM)

Height of support above ground	52.5 ft. (16 m.) approx.
Distance between mast centers	39.4 ft. (12 m.)
Conductor spacing	19.7 ft. (6 m.)

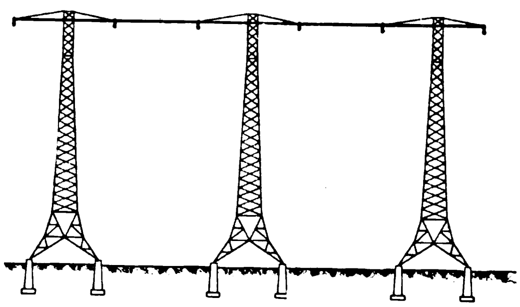

FIG. 2—TYPE OF STEEL ANCHOR STRUCTUREF OR TWO 220-KV., THREE-PHASE CIRCUITS

(TROLLHATTAN-VASTERAS LINE OF SWEDISH STATE POWER SYSTEM)

Height of support above ground	52.5 ft. (16 m.) approx.
Distance between mast centers	39.4 ft. (12 m.)
Conductor spacing	19.7 ft. (6 m.)

1. Whitehall Securities Corporation, Ltd., London, England.

Presented at the Regional Meeting of District No. 1 of the A. I. E. E., Niagara Falls, N. Y., May 26-28, 1926.

220 kv.; but those built to date will be operated at a reduced voltage until the higher voltage is required.

Two types of towers used in the construction of the Western Trunk Line of the Swedish State System between Trollhattan and Vasteras are shown in Figs. 1 and 2.

ITALY

Italy shares with Switzerland the run-off from the Swiss-Italian Alps, which provides an abundant source of water-power, and here, as well as in Switzerland, rapid progress has been made in hydroelectric development and transmission lines.

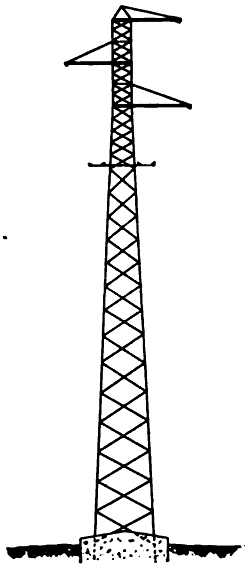

FIG. 3—TYPE OF STANDARD STEEL TOWER FOR ONE 125-KV., THREE-PHASE CIRCUIT

(TEMU-CEDEGOLO LINE OF THE SOC. GEN. ELLETTA DELL 'ADAMELLO)

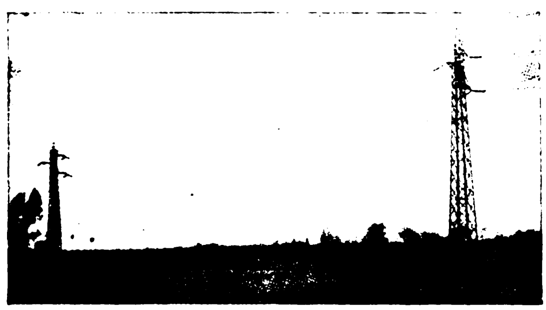

FIG. 4—TYPE OF STANDARD STEEL TOWER FOR ONE 130-KV., THREE-PHASE CIRCUIT

(REGGIO-EMILIA LINE OF THE SOC. ELETTA. INTERREGUIALE CISALPINA)

Height to lowest cross arm	69 ft. (21 m.)
Average span	820 ft. (250 m.)
Conductor spacing	17.5 ft. (5.3 m.)
Weight of tower	4800 lb. (2200 kilos)

Because of the rugged topography of Northern Italy, transmission lines must be largely confined to the narrow valleys, in some of which there are as many as ten parallel multicircuit lines of voltages ranging from 2-kv. to 130-kv.

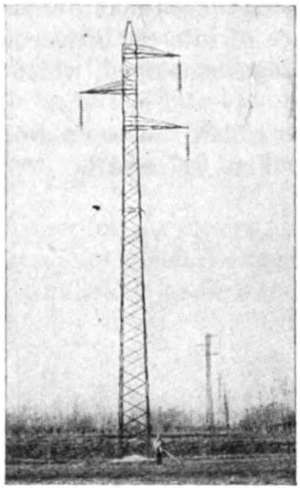

FIG. 5—TYPE OF STANDARD STEEL TOWER FOR ONE 140-KV., THREE-PHASE CIRCUIT

(OVESCA-ARQUATA LINE OF THE SOC. GEN. ITALIANA "EDISON DI ELETTA" MILAN)

Average span 656 ft. (200 m.)

The types of tower used on three of the more interesting lines recently built in Italy are shown in Figs. 3, 4, and 5.

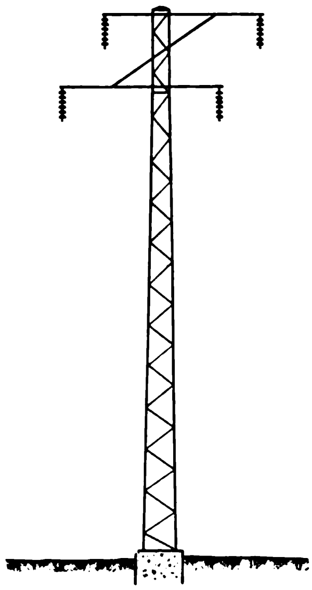

FIG. 6—TYPE OF STANDARD STEEL TOWER FOR ONE 135-KV., THREE-PHASE, 50-CYCLE CIRCUIT AND FOUR 66-KV., SINGLE-PHASE 16-2/3-CYCLE CIRCUITS

(AMSTEG-IMMENSEE LINE OF THE SWISS FEDERAL RAILWAYS)

Length of line 29 mi. (47 km.)
Average span 787 ft. (240 m.)
Maximum span 1610 ft. (490 m.) with 620 ft. (190 m.) difference in elevation of supports
Conductors aluminum steel reinforced except bronze on long spans
Ground wire galvanized steel

SWITZERLAND

The most important recently constructed transmission lines in Switzerland have been built by the

Swiss Federal Railways, in conjunction with the electrification of that system. Certain of these lines are jointly owned by the Federal Railways and the Swiss Power Transmission Co., Ltd., of Berne.

These lines are of interest on account of the high single-phase voltages employed, which are 66 kv. and 132 kv.

The types of standard tower used on three of these lines are shown in Figs. 6, 7, and 8.

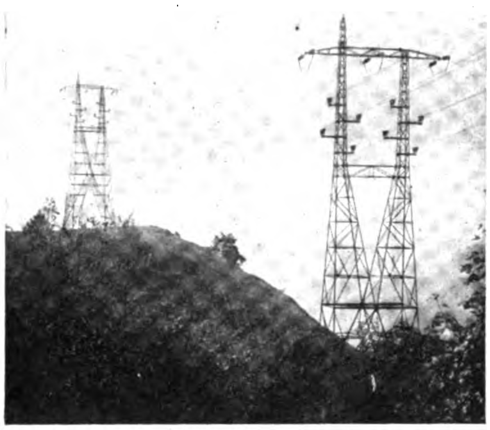

FIG. 7—TYPE OF STANDARD STEEL TOWER FOR TWO 132-KV., 16-2/3-CYCLE, SINGLE-PHASE CIRCUITS

Length of line	134 mi. (216 km.)
Height to lowest conductor	28 ft. (8.5 m.)
Average span	737 ft. (216 m.)

Conductors aluminum steel reinforced.
Insulators, suspension type, seven units.
Ground wire, copper clad steel.

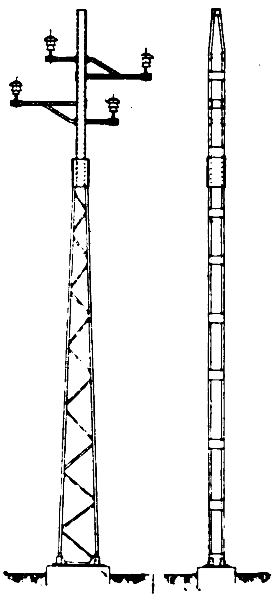

FIG. 8—TYPE OF STEEL TOWER USED ON STANDARD TRANSMISSION LINES FOR TWO 66-KV., SINGLE-PHASE, 16-2/3-CYCLE CIRCUITS

(SWISS FEDERAL RAILWAYS)

Length constructed. 155 mi. (250 km.)
Average span. 410 ft. (125 m.)
Conductors, stranded copper
Ground wire, galvanized steel

SPAIN

Concrete poles, Fig. 9, with concrete cross-arms cast integral are used on the 70-kv. lines of the Cia Anonima Mengemor, Spain.

A photograph of one of the anchor towers of the 130-kv.

FIG. 9—TYPE OF CONCRETE LINE SUPPORT ON 70-KV. LINES OF CIA ANONIMA MENGEMOR, SPAIN

Average span 328 ft. (100 m.)

Albaseta - Dos Aquas line of the Sociedad Anonima Hidroelectrica Espanola is shown in Fig. 10.

GERMANY

The 100-kv. Lauta-Trattendorf line in Germany is worthy of serious consideration as a precedent in the construction of high-tension lines on public highways.

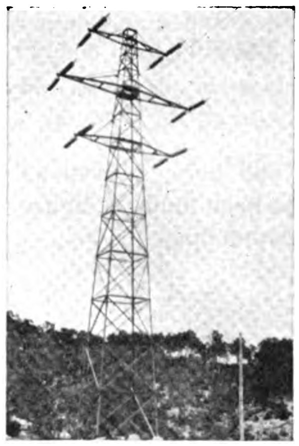

FIG. 10—TYPE OF STEEL ANCHOR TOWER ON 130-KV. ALBASETA-DOS AQUAS LINE OF THE SOCIEDAD ANONIMA HYDROELECTRICA ESPONOLA

Average span 656 ft. (200 m.)

While few municipal authorities would sanction the construction of lines of such voltages in the public street, the factor of safety is no doubt higher than that common to overhead contact wires for tramway systems.

A typical view of this line is shown in Fig. 11.

ENGLAND

In England, with the exception of one group of companies in the North, which operates about 1000 mi. of high-tension lines, extensive overhead transmission

systems have not been developed. This is perhaps due to the wide distribution of its coal deposits which renders transmission less effective than in places where power markets are widely separated from sources of fuel.

A further explanation of the relatively few overhead lines constructed in England is to be found in the well-established practise of placing power lines underground, which has to a large extent been forced by strict Government and Municipal regulations, and by the difficulty and delay experienced in securing suitable rights of way.

Numerous attempts have been made in England to establish a policy with regard to national superpower developments, beginning as early as 1914. The principal schemes have been included in reports made in 1918 by the Electric Power Supply Committee (known as "The Williamson Report") and the report of the Commission appointed by the Minister of Transport

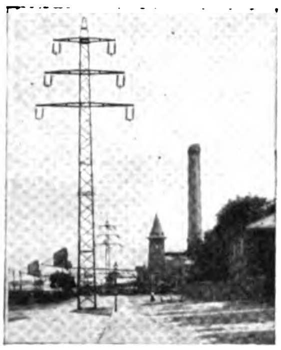

Fig. 11—Type of Steel Support on 100-Kv. Lauta-Trattendorf-Moabit Line in Germany

Height of tower, 92 ft. (28 m.)
Height to lowest crossarm 65 ft. (19.8 m.)
Conductor spacing (3.1 m.)
Conductors—copper
Insulators, two strings of six Kapp units
Minimum clearance between line and buildings (26 m.)

to review the national problem of the supply of electric energy (known as The Weir Report) which was published early in the year 1926.

The scope of the report covers a period to the year 1940 when the consumption in Great Britain, now growing at the rate of 19 per cent per annum, would be raised from the present figure of 110 units per capita to 500 units, the rate now obtaining in the United States; but it is expected that the 500-unit figure may be reached before that date.

The basic recommendations of the Committee are as follows:

a. To reduce to 58 in number 438 of the power stations in Great Britain, many of which are small and unsuited to generate power economically. The 58 stations, 28 of which would be of capital order and 30 of secondary order, would be designed to produce electrical energy at a minimum cost. (These 438 stations do not include 48 stations owned by railway companies, and operated particularly for railway electrification.)

b. To establish a gridiron (high-tension transmission network) for the purposes of interconnecting the 58 power stations.

c. Provision for the output of the 58 power stations to be turned into the gridiron at a predetermined price per unit with privilege of purchasing for local supply, at the price billed to the gridiron.

d. Provision for the closing down of nearly 400 generating plants which is expected to be brought about automatically as the companies operating them would be able to purchase power from the gridiron at a cost less than that of private generation.

e. Provision for the establishment in communities, not at present supplied with electricity, for local authorities, who would distribute power purchased from the gridiron in such areas.

f. Recommendations in favor of the standardization of frequency affecting a few of the larger suppliers. Subject to further investigations this may be undertaken at public expense at a total gross cost approximately £10,500,000, and a net cost of £8,000,000 after allowing for expenditure represented by useful additions to plant capacity.

It is estimated that the total expenditure to 1940 would extend upward to £250,000,000 and that with proper coordination and assistance from the Government, this figure is substantially less than would result if developments were allowed to continue under existing conditions.

It is further estimated that one-half of this amount of new money would be required in connection with the development of distribution systems, this portion of capital to be provided by local authorities, power or distribution companies, as at present.

It is stated that the remaining half of the capital can be conveniently divided into two sections:

First. The amount necessary to construct the high-tension network for bulk transmission, plus working capital, reserve, and interest capitalized for a period of five years, at which date the net earnings from the gridiron would be expected to be sufficient to cover all obligations.

It is estimated that the sum of £25,000,000 would be required for gridiron expenditure at the end of five years from the date the scheme might be put into operation.

Second. The amount necessary to provide local authorities, or other authorized persons with capital required for the erection of new capital generating stations, or additions to present stations. Within certain limits capital and interest would be guaranteed by the Government.

The report points out the following conditions obtaining in Great Britain at the time of its issue.

Average price charged to consumers for all purposes	2.047d. (pence)
Gross revenue	£34,256,000
Revenue per £100 invested	£21.2
Plant installed	3,096,535 kw.
Maximum load	1,844,000 kw.
Spare plant	68 per cent of maximum load
Units sold per annum	4,016,000,000
Units sold per head of population	110
Annual load factor	24.9 per cent
Capital invested per kw. for Generation	£23.8
Capital invested per kw. for distribution	£28.5
Total capital investment per kw. for generation and distribution	£52.3

It is estimated that as a result of economies to be effected by the recommendations of the committee, the position in the year 1940, or whenever the national consumption has been raised to 500 units per head, would approximate the following:

Units sold per capita	500
Maximum load	8,135,000 kw.
Kw. installed	10,000,000 kw.
Spare plant	25 per cent
Units sold	21,385,000,000 (kw-hr.)
Annual load factor	30 per cent
Total capital invested for generation	£127,000,000
Capital invested for "Grid Iron" transmission	£29,000,000
Capital invested for distribution	£243,500,000
Total revenue	£88,100,000
Average price per unit	1 d. (pence) or under
Number of capital stations	28
Number of secondary stations	30
Total number of stations	58

In the annex to Appendix I of the report there appears an interesting estimate of the cost of power stations of 133,000-kw. installed capacity, capable of meeting maximum load conditions of 100,000 kw., which is said to be based on contracts for the Barking Station of the County of London Electric Supply Co., Ltd., one of the principal superpower stations constructed in England to date.

	£ per kw.
308 acres of ground at Barking	0.733
Civil engineering works, piling, wharfs, railway sidings, water culverts, screens and foundations	1.880
Buildings and cranes	1.722
Turbo alternators and accessories	3.950
Boilers and accessories, and ash-removal plant	3.464
Switchgear and cables	0.683
Step-up transformers and station auxiliaries	0.593
Piping	0.465
Coal-storage equipment, consisting of cranes, locomotives, and cars	0.148
Sundries, including batteries and charging sets, oil coolers and pumps, oil filter plant, auxiliary sets and wiring and fittings	0.301
	£13.939
Engineering supervision, legal and incidental expenditure (5 per cent)	0.697
	£14.636

It is estimated that the average total cost of generation per kw. on the basis of coal at 16s. (shilling) per ton would be 0.3456d. (pence) with an additional capital and operating charge on main transmission lines of 0.0291d. (pence) or a total of 0.3747d. (pence) per unit sold over the gridiron.

Local distribution expenditure, including capital charges, local management and taxes, is further taken at 0.5000d. or 0.8747d. per unit at the distribution system, which is raised to 1.029d. on the basis of 85 per cent distribution efficiency.

It is understood that the assumed efficiency of 85 per cent has caused some amount of criticism.

According to the report the average cost of 1d. per unit would not be a uniform price maintained throughout Great Britain, but would vary according to local generating conditions, the amount of transmission network involved, and the distribution expense.

The estimated figure for Scotland is given as 1.038d. per unit, and that for Central England as 1.029d. per unit.

A striking feature of the report is a recommendation that the transmission network be owned and controlled by a new body created by Act of Parliament, termed the Central Electricity Board, which would purchase and dispose of energy from all of the interconnected stations, or alternatively charge for the use of the transmission network, or a further alternative according to which all generating stations would be purchased and the less efficient ones closed down, leaving the best stations to be operated by the Board, thus bringing all generation and transmission under the control of a single body.

Objection has been raised in some quarters on the ground that acceptance of the latter recommendations might be a step toward government ownership. On this account an opposition movement is on foot to prevent the bill being passed by Parliament.

The report is noteworthy as constituting the largest scheme ever proposed for the unification and extension of electric service for the definite purpose of reducing the cost of electric energy to a community.

In general, the measure seems to be popular, and there is every indication that some such Bill will be authorized by Parliament in the near future as it appears to be agreed that only through the intervention of Government interest can such a system be brought into being on account of the great diversity of interests involved.

The report shows typical curves of load and load factor, but no maps or other data are included to show details of the interconnecting network.

A transmission voltage of 33 kv. seems to be considered sufficiently high for average English conditions, at present, and has been more or less standardized for both overhead and underground lines. Some 66-kv. lines have been built and still higher voltages will no doubt be employed if extensive electrification plans are adopted.

Typical views of some of the high-tension trans-

mission lines recently constructed in England are shown in Figs. 12, 13 and 14.

Fig. 15 shows the dead-end structure of a 66-kv. line and its junction with 66-kv., single-conductor cables leading to the transformers.

Average span 330 ft. (100 m.)

cable transmissions of relatively high voltage are the North East Coast Power Co., Newcastle-on-Tyne, England, 66 kv., Union D'Electricité Paris, France,

60 kv., and Provincial Electricity Works Bloemendaal Holland, 55 kv.

There is also a considerable amount of 33-kv. cable in operation in England.

In Italy a 130-kv. experimental cable of the Pirelli type has been in operation for something over a year with promising results.

One source of trouble which has been responsible for a considerable number of breakdowns in high-

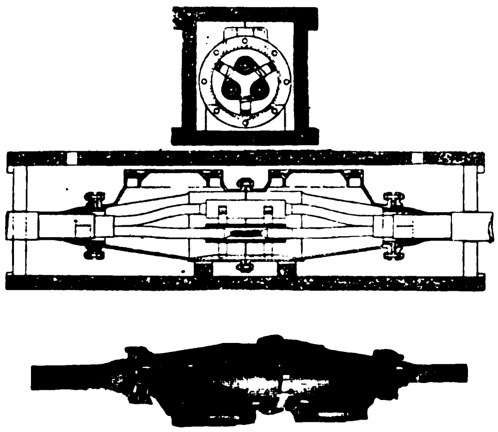

FIG. 17—THREE-CONDUCTOR, 50-KV. CABLE JOINT OF BRITISH MANUFACTURE

tension cable installations is the result of pressure differences within the sealed cable, where considerable difference in elevation exists throughout a part or whole of its length.

Pressure differences are created if there is any movement of compound used in the cable or its joints and

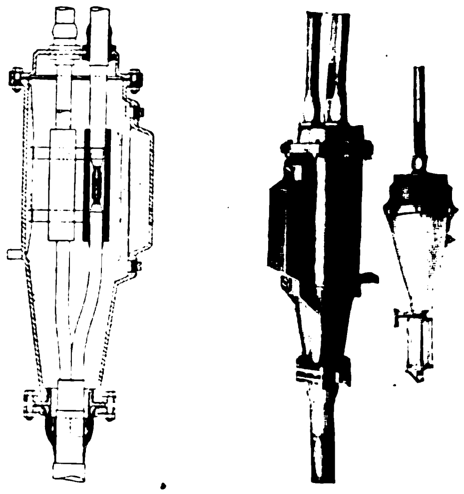

FIG. 18—THREE-CONDUCTOR, 50-KV. TRIFURCATING BOX WITH SINGLE-CONDUCTOR TAILS AND SEALING END, OF BRITISH MANUFACTURE

any voids caused by such movement of the insulating compound must necessarily weaken the insulation, resulting in failure.

This has led to the development of a type of joint design for filling under pressure, which is expected to ensure complete filling and to prevent voids, but the writer is not able to say whether or not this method has been successful.

Investigations are in progress to determine the feasibility of constructing supertension cables in which a uniform potential gradient would be maintained by means of metallic sheathes, placed between layers of insulation and connected to taps in the transformer winding.[2]

Cables so constructed would be expected to run high in cost, and the splicing and sealing of the ends would seem to present unusual difficulties. However, it is not improbable that continued investigation may develop a cable with solid insulation for supertension voltages at a cost no greater than that of a steel tower line, particularly if there is a saving in cost of right of way, as might be expected in congested districts.

A three-conductor, 50-kv. cable joint of British manufacture is shown in Fig. 17 and in Fig. 18 and a

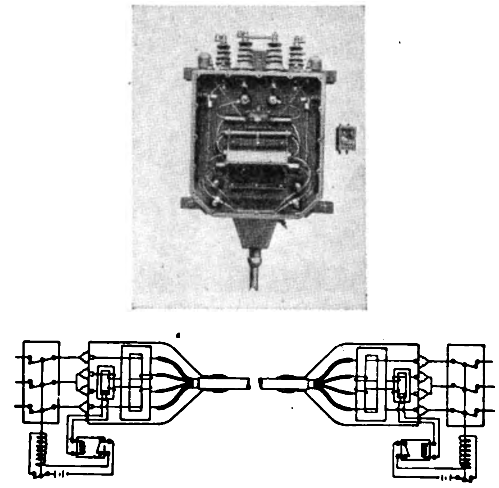

FIG. 19—CONNECTION DIAGRAM OF CALENDER HUNTER FOUR-CONDUCTOR SYSTEM OF CURRENT BALANCED CABLE PROTECTION AND INTERIOR VIEW OF A SEALING END SHOWING PHYSICAL ARRANGEMENT OF BALANCING TRANSFORMER

50-kv. trifurcating box with its single-conductor tails and sealing end.

Practically all distribution in England is accomplished by means of underground cables.

The principal distribution problem is to be found in the London area which is served by about 80 power plants.

A frequency of 50 cycles predominates, but there is considerable diversity as regards phase and voltage.

Low-tension distribution is direct current, two- and three-wire, and alternating current with various systems of connections. Lighting voltages vary from 100 to 240 volts, while power service voltages extend to something over 500 volts. Bulk supply is sold at high-tension voltage.

The main feeder cables of power systems are fre-

2. See paper by A. M. Taylor in *Journ. I. E. E.*, London, England, No. 315, February, 1923.

quently protected by means of current balance, this being accomplished in various ways. In the case of two parallel feeders, the current in one is balanced against the current in the other by means of differential relays which open the circuit-breakers upon a very slight difference in current value.

Cables are in use with six conductors, three of which in a three-phase system are similarly balanced against the remaining three.

A new form of cable specially designed for balanced

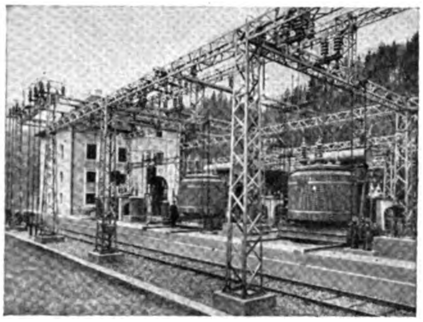

Fig. 20—Shilbrugg Substation of the Swiss Federal Railways, Showing 66-Kv., Single-Phase Construction

protection, and which costs somewhat less than six-core cable, has recently been brought out. This system utilizes a special form of four-conductor cable in which two conductors have one-half of the cross-section of the remaining two, and current transformers of special design contained in the sealing ends at each end of the cable. These transformers function to cause a current to flow in a separate winding when the current in the different phases becomes unbalanced. The

Fig. 21—12,000-Kv-a. Outdoor Transformer Installation of the Northeast Coast Power Co. at Dunstan, England

resultant current is employed to operate a relay arranged to open the circuit breakers.

A diagram showing the connections of the special balancing transformers and relay and the interior of one of the sealing ends is shown in Fig. 19.

High-Tension Equipment

Until quite recently European engineers have conformed to a universal practise of placing high-tension equipment indoors, but with the use of larger units and higher voltages, the outdoor substation is beginnnig to make its appearance.

The recently constructed substations of the Swiss Federal Railways are outdoor type and are relatively simple because of the use of the single-phase system of power transmission and distribution to track circuits.

A photograph of the Shilbrugg substation of the Swiss Federal Railways near Zurich is shown in Fig. 20.

Fig. 21 shows a recent outdoor transformer installation in England with its 66-kv., single-core cable connection. The sealing end for the 66-kv. cable may be seen in the foreground, bolted directly to the transformer tank.

The more prominent electrical manufacturers in England and on the Continent have developed complete lines of equipment for voltages up to 130 kv., while some are prepared to offer equipment for higher voltages.

Lightning protection seems to have received considerable attention on the Continent. The predominat-

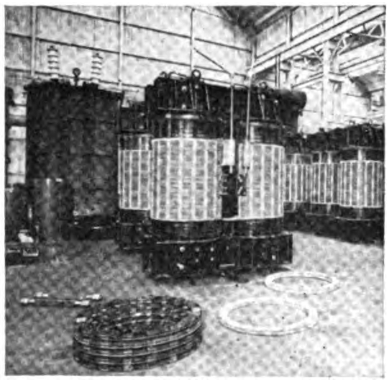

Fig. 22—12,500-Kv-a., 110-12-Kv., Single-Phase, Water-Cooled Transformer Units of British Manufacture

ing type of arrester has horn gaps in series with water co.umns contained in vertical porcelain receptacles, which are mounted on high-tension insulators. In some cases arresters of the electrolytic and oxide film types of American manufacture are used.

Lightning protection seems to have caused very little concern in England. A length of cable at the end of a high-voltage line is considered by many British engineers to be an excellent method of lightning protection.

On the Continent there seems to have been some fear regarding the solid grounding of high-tension neutrals, although the advantages of grounding are recognized. In some instances a compromise is resorted to, by placing a horn gap in series with the neutral-ground connection. The horn gap is set sufficiently close to break down if a ground occurs.

It is almost universal practise on the Continent to design transformers for forced oil cooling, as this type of transformer costs somewhat less than the water-cooled type. Water-cooled transformers are, however, built in considerable quantities, both on the

Continent and in England, as they are sometimes to be preferred.

Fig. 22 shows part of a group of 12—110-kv:, 12,500-kv-a. single-phase water-cooled transformers recently built in England for shipment to India.

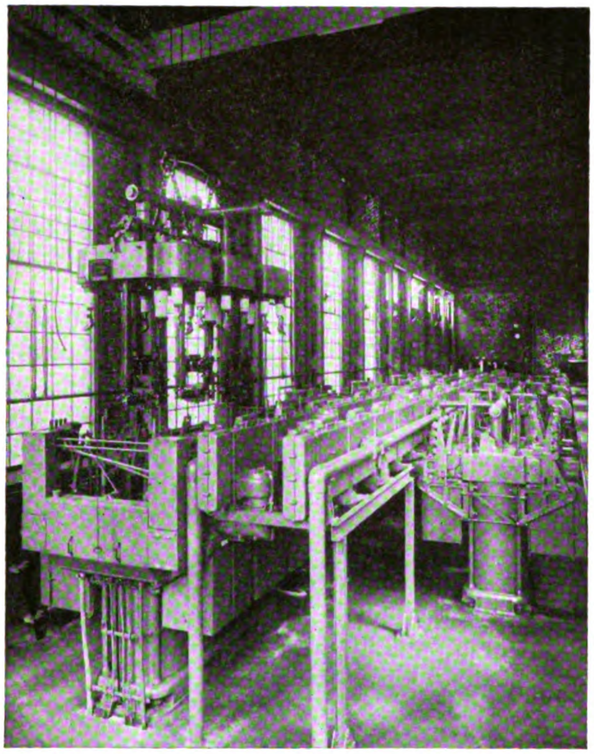

Fig. 23—Portion of 33-Kv., Iron-Clad Switchgear Installed at Barking Station of the County of London Electricity Supply Co.

(On back of Photo)

Showing one-quarter of the ultimate switchgear. In the foreground is seen the sealing off of the end of the busbars and the tail end of the vent pipe leading down through the floor to the outside of the building, but in this case the drawout portion of the main oil circuit breaker is shown removed and suspended above its panel. The operation is interlocked with the crane to ensure that all conductors are dead before it commences.

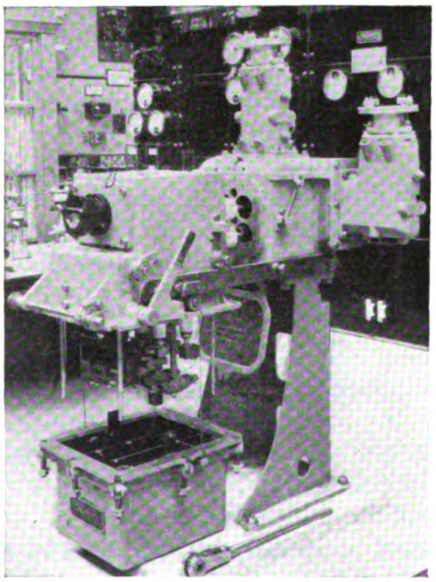

Fig. 24—Hand-Operated, Armor-Clad, Flame-Proof, Draw-Out Type Feeder Pillar for Industrial and Mining Service

Circuit breaker tank opened for inspection

There have been developed in England very complete designs of fully enclosed, or co-called "Armour clad" switchgear, for voltages as high as 33 kv.

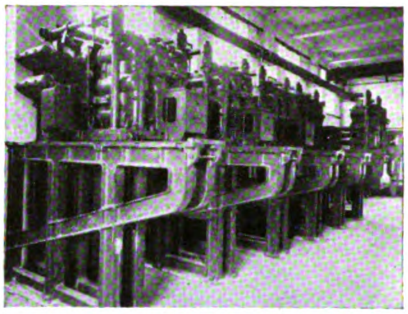

Fig. 25—Electrically-Operated, Armour-Clad Switch-Gear of Draw-Out Type for Power Station Service, 500,000 Arc Kv-a. Rupturing Capacity

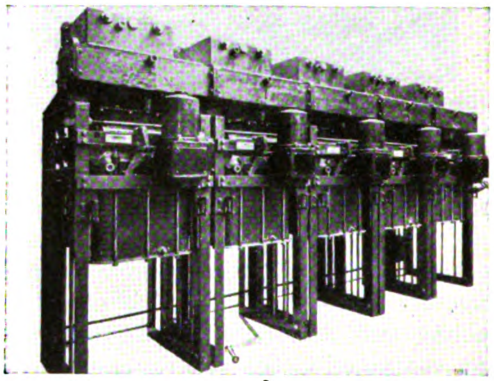

Fig. 26—Electrically-Operated, Armour-Clad Switch-gear of the Drop Tank Type of 250,000 Arc Kv-a. Rupturing Capacity Installed at Talbot Road Power Station, Nottingham, England

When circuit breaker is open tank may be lowered for inspection by means of the crank shown in the foreground. During the lowering process all leads are disconnected and live parts protected automatically.

Fig. 27—Self-Contained, Armour-Clad Distribution Substation of British Manufacture

The recent switchgear installation at the Barking Station of the County of London Electricity Supply Co. introduces one of the most modern developments of this type of gear, which is designed for an operating voltage of 33 kv. and rupturing capacity of 1,500,000 arc-kv-a.

Fig. 23 shows one quarter of this gear in place, with one of the circuit breakers withdrawn. In the foreground may be seen the sealing ends of the compound-filled busbar components and the gas-vent pipes leading through the floor to the outside of the building.

One of the features of the Barking Station gear is the very complete system of interlocks, which has been developed to such a point that it is practically impossible to perform any switching operation in the wrong sequence. To make the system fully complete each section is interlocked with the crane so that no circuit-breaker mechanism can be removed from its position until all connections have been made dead.

This type of gear has been extensively developed to cover all classes of power, mining and industrial requirements.

Three examples of anchor-clad switchgear are shown in Figs. 24, 25 and 26.

A complete armour-clad substation containing high-tension switches, distribution transformer and low-tension fuses is shown in Fig. 27.

Conclusion

The writer wishes to express his appreciation to all who furnished or assisted in securing information or illustrations contained in this paper.

Automatic and Supervisory Control of Hydroelectric Generating Stations

BY FRANK V. SMITH[1]

Associate, A. I. E. E.

Synopsis.—*The paper describes the application of automatic equipment and supervisory control to a number of interesting hydroelectric installations.*

A brief description is first given of the operation of standard equipment, the function performed by it and the protective measures provided. Then several typical stations involving single units, multiple units, self-synchronizing and automatic synchronizing are described, together with some test results of the current surges occurring during the starting operations. The paper closes with some comments on the high-speed, synchronous relay type of supervisory control and remote metering.

* * * * *

General

THE installation of hydroelectric stations equipped with automatic or supervisory control has become so widespread that it may not be out of place, at this time, to review some of the more interesting applications in order to show the variety of problems confronting the switchboard engineer and the methods of handling them. A brief description will be given of the scheme of control that has become more or less standardized for this type of station and then an analysis of several installations.

In general, the equipment is either entirely automatic or operated by means of supervisory control from a remote point, the latter scheme becoming more and more popular because of its greater flexibility.

The simplest kind of supervisory control, known as the Audible Type, is used because of the limited number of operations that have to be performed and the call of economy. Only two wires are necessary for this type. A standard telephone, together with a box containing a number of line keys and a dial, similar to that used in automatic telephone equipment, is required at the dispatching point and a relay cabinet at the generator end. Any number of stations up to ten can be controlled with the same pair of wires looping through them. If separate lines are run out radially from the dispatcher, a key is required for each line to connect it to the supervisory equipment.

Every number dialed sends a train of impulses over the line which, by means of rotary selector switches, perform a certain operation in the distant station and an answer back is received through the telephone (or loud speaker) in the form of a number of busses of different tones, the indication being repeated until another number is dialed or the line disconnected. Fig. 1 shows the complete equipment with the exception of the telephone. At the right is the dispatcher's box with dial and on the left the relay cabinet installed in the remote station. The microphone with low- and high-tone buzzers can be clearly seen while at the extreme left are the rotary switches. A battery of 16 volts is required at the generating station while 110 volts is generally used at the dispatcher's end.

The first operation is to connect the correct station to the supervisory control. This is done by throwing the line key and dialing the number of the station desired—perhaps No. 3. A selector switch then operates in each station stepping to Point 3. This is so arranged that when it stops on any point other than the number of its own station, it sets up a lock-out which prevents further action; but at No. 3 it operates another rotary switch that completes a circuit to a buzzer three times every revolution giving three buzzes in the telephone

1. Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa.

Presented at the Regional Meeting of District No. 1 of the A. I. E. E., Niagara Falls, N. Y., May 26-28, 1926.

which are repeated until the circuit is interrupted from the dispatching station by further dialing.

The next operation may be to determine the head of water in the forebay. The maximum variation in head is divided into 10 parts with a float switch making contact as it moves over the range and these points are connected to a similar rotary switch so that on checking water head a number of buzzes are heard indicating the point on the scale at which the float stands.

The dialing of another number will set the master

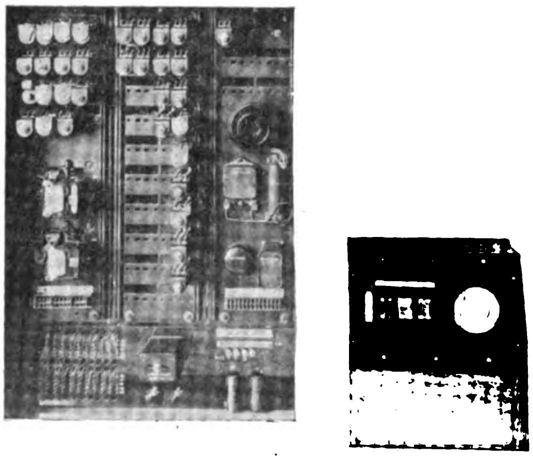

Fig. 1—Audible Type Supervisory Control

relay in the station in operation and the unit will start up and put itself on the line. In stations which are entirely automatic, this master element is energized by such a device as a time clock, frequency relay, float switch or something of the kind which starts the machine when certain predetermined conditions exist.

In general the automatic equipment is arranged to perform the following functions:

a. Start the unit, provided normal conditions exist, upon the operation of the master-starting element

b. Stop the unit by means of the master element

c. Protect against generator overvoltage

d. Protect against motoring of the generator

e. Prevent the opening of the line circuit breaker on short time periods of low a-c. voltage

f. Protect against discharge of the battery. Battery control with automatic means for charging is the most reliable method available because of its complete independence from the a-c. system with its occasional voltage dips.

g. Shut-down the unit temporarily if:

1. The line is short-circuited or overloaded to a point that the machine voltage drops below 80 per cent of normal for several seconds
2. The machine windings tend to overheat
3. The unit overspeeds
4. The unit is caused to operate on a reverse, single or badly unbalanced phase line.

h. Shut-down and lock-out the unit if:

1. A bearing overheats
2. The generator field fails
3. The oil pressure in the governor falls below a safe value
4. The differential relays operate

i. On normal shut-down, the oil circuit breaker and field contactor are prevented from opening until the gates reach the no-load running position. This gradually transfers load to other units on the system and prevents sudden dropping of load on the automatic generator.

j. Prevent the generator from starting if:

1. The unit has been locked out by any function under *h*
2. Conditions as listed under *g* have not been righted

The unit may be provided with a periodic relay so arranged that in event of its being shut-down temporarily as under *g* it will attempt to start only a predetermined number of times and then lock itself out.

The items listed under *h* represent serious troubles in the machine and operate an annunciator lock-out relay which has a series of targets, one for each device, and tells at a glance the cause of the shut-down.

Where supervisory control is used, a warning signal is sounded in the dispatching station whereupon the cause of the trouble can be checked and the station started again if it is of a minor nature.

Single Unit Stations

One of the most interesting cases of the application of this type of control is to be found on a property of the Interstate Public Service Company in the Middle West. Here there is an old barge canal on which are located five hydroelectric stations each containing one vertical

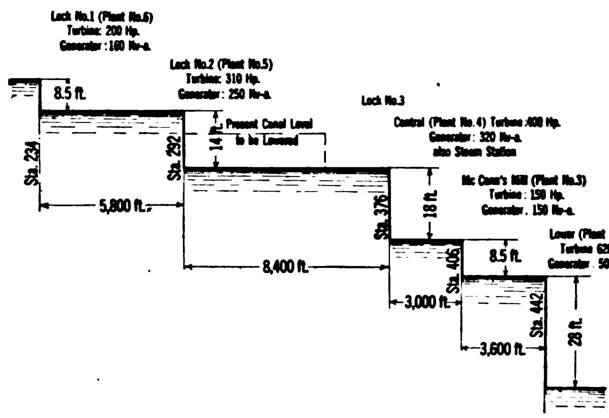

Fig. 2—Interstate Public Service Company Canal Profile

generator. These are known as plants No. 2, 3, 4, 5 and 6 stretched over a canal length of about four miles with machines rated at 500, 150, 312, 250 and 150 kv-a. respectively. Plant No. 4 is the Central Plant and is used as the dispatching point, as a steam station is also located close to the canal and operators are therefore nearby. All machines generate at 2400 volts and are tied together and to the rest of the system with a transmission line at this voltage. Each machine has a direct-connected exciter of ample capacity. Fig. 2 shows the lay-out of the canal.

The four automatic stations are controlled from Plant No. 4, out of which one pair of lines runs to Plants No. 5 and No. 6 and another pair to No. 2 and No. 3. Plant No. 4, itself, is manually operated.

When starting up a station, the key to connect the East or West line to the supervisory is thrown at the control desk and the number of the desired station is dialed. On receiving assurance that the correct plant is connected to the line a check is made of the water-level. If this is suitable the station is started by dialing the proper number. A solenoid on the governor is then energized and the gates begin to open till a point is reached to give approximately normal speed at no load. As the wheel comes up, the exciter, which is not yet connected to the a-c. generator field but has most of its own rheostat short-circuited, builds up its voltage and closes the main line breaker at approximately synchronous speed. As the generator is provided with damper windings it pulls rapidly into step, assisted by the field excitation which is thrown on by an auxiliary switch on the main breaker. The generator then operates in the usual manner under the control of a standard vibrating regulator. This self-synchronizing method of putting a machine on the line is the simplest scheme that is available and even eliminates the necessity of a speed switch to determine the point at which the breaker is closed—this point being set by exciter voltage. As the system is very large compared with the size of the units, no appreciable shock is felt on the line when the machine is closed.

In order to utilize all the water available, the three smaller units at Dams Nos. 3, 5, and 6 operate under float type of load control; the gate opening depending entirely on the head of water available. On the larger units the usual type of speed governor is used with the addition of a float attachment for limiting the load on low head.

The supervisory control performs the usual functions of starting and stopping the units and reading the head of water, power output (determined from the gate opening) and breaker position. In addition, a point is furnished for voltage control; this is provided by means of a contactor which short-circuits a section of the voltage regulating rheostat on the generator and, in effect, recalibrates it for a different voltage. Two trouble horns are furnished in the dispatching station, one for the east and one for the west line. When any machine locks out due to operation of its protective equipment, the horn sounds until the station in trouble is located by means of the supervisory system.

On another part of this system there are now being installed two generators rated at 300 kv-a. and 400 kv-a., 2300 volts in different stations a few miles apart. These are to be entirely automatic, starting and stopping by means of a combination of float switch and time-clock so arranged that the machines will operate according to a predetermined time schedule providing the water-level is within the proper limits.

Multiple-Unit Stations

In these cases there has been but one generator per station. However, installations of two or three machines in the same plant are quite common and give rise to no particular problem. When supervisory control is used, the separate units are handled almost independently as if they were in different stations; the load and breaker positions, etc., of each unit are read separately, although, of course, one water-level indicator is sufficient for the station. When under complete automatic control one machine is given preference so that it will always start first and the others will follow in order as conditions demand. A simple knife switch is generally supplied so that the No. 1 machine can be changed at stated intervals and thus distribute the service over the various units. Sometimes, in order to

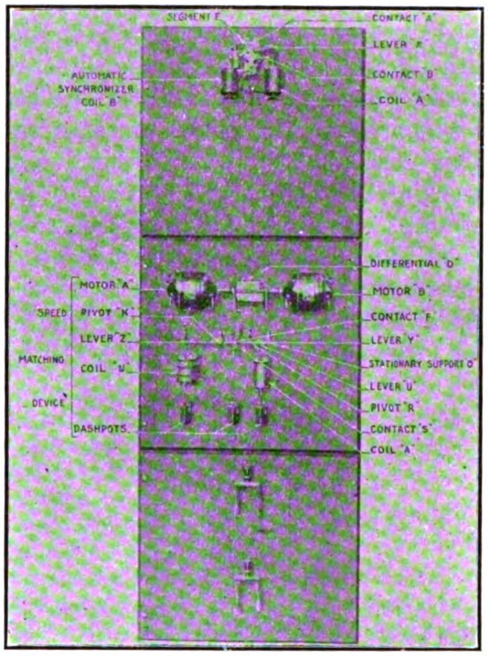

Fig. 3—Automatic Synchronizer

obtain the maximum output from the station, arrangements are made so that as many machines as possible will operate at their maximum points of efficiency rather than distribute the load equally over all units.

One of the most interesting applications in the country is to be found on the property of the Wisconsin Public Service Company on the Peshitgo River. Here, there is a string of four plants at Caldron Falls, High Falls, Johnson Falls and Sandstone Rapids, connected by a 66,000-volt line which runs south to Green Bay. High Falls is a manually operated station of 8750-kv-a. from which the other three are controlled.

Automatic Synchronizing and Self-Synchronizing

The first automatic to be installed was Johnson Falls which contains two 2200-kv-a., 2400-volt, 150-rev. per min. vertical machines with direct-connected exciters and is located three and one-half miles down

the river from High Falls. Since High Falls would be the only station in operation when the machines at Johnson Falls were started up it was felt that if the usual self-synchronizing scheme of throwing the generator on the line without field at approximately synchronous speed were utilized, the bump on the system might be objectionable, and it was decided to make use of the automatic synchronizer. In any case in which the incoming generator capacity is an appreciable percentage of the system kv-a. the use of the automatic synchronizer is essential if smooth operation is to be secured, in fact, in some cases where the machine is on the end of a long line with limited capacity an attempt to throw it on without synchronizing might well produce such a drop in voltage as to allow any synchronous motors on the system to drop out of step.

The automatic synchronizer shown in Fig. 3 is composed of two parts—the speed matcher and the synchronizer proper. The generator is brought up to speed with its field excited from the direct-connected exciter under the control of its voltage regulator and as it nears synchronism the speed matcher comes into play. This consists of a pair of small single-phase motors working through a differential to a contact-making device. One motor is connected to the leads of the incoming machine and the other to the bus. Depending on whether the machine is below or above synchronism, contact is made through the differential to raise or lower the speed of the water-wheel through

Fig. 4—Control Panel for Rheostatic Regulator

the electrically operated governor so that it is held at synchronous speed. An anti-hunting device prevents oscillations. The automatic synchronizer then functions to close the breaker when exactly in phase. This consists of two solenoids working through a lever mechanism and an oscillating segmental contact. It can be seen mounted on the top of the panel. One solenoid is arranged with coils excited from a potential transformer connected in such a way as to have a maximum pull when the voltage of the machine is in phase with the bus and zero pull when directly out of phase. The other solenoid is connected in the reverse manner so that as the machine approaches synchro-

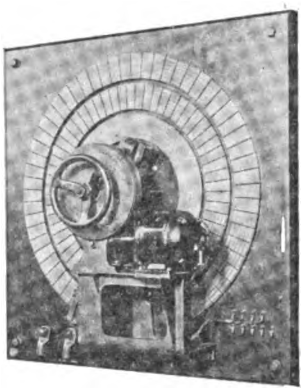

Fig. 5—High Speed Face Plate for Rheostatic Regulator

nism, the pull of the two solenoids reaches a maximum alternately and oscillation takes place in the lever mechanism. The frequency of these oscillations falls as the machine approaches synchronism and when it reaches that corresponding to a complete revolution of a synchroscope needle in approximately five seconds the oscillating segment makes contact long enough to complete a circuit to the control relay and close the machine breaker connecting it to the line. The machine then continues to operate when under the control of its voltage regulator. Synchronizing by this means is much more rapid and more accurate than could be done by hand.

An interesting point in connection with the installation is the use on the generator of the high speed face-plate rheostatic voltage regulator rather than the vibrating type. This regulator is coming into very common use in hydro stations—particularly automatic stations—because of its extreme simplicity and very satisfactory operation. The exciter voltage is maintained constant and regulation takes place entirely on the main field rheostat. A typical control panel is shown in Fig. 4 and the motor-operated face plate in Fig. 5. The forward and reversing contactors of the motor are shown on the top of the panel while the control element proper is below. Variation in bus voltage, working through the lower mechanism, results in rapid cutting in or out of resistance with suitable anti-hunting devices to prevent over-travel of the motor. In this regulator the time element of the exciter field is eliminated so that its speed of operation is quite comparable with the vibrating type and is particularly applicable where heavy field currents necessitate a large number of relays on the vibrating regulator.

The second station to be installed on this system was

Caldron Falls about seven mi. up the river from High Falls where there are two 4000-kv-a., 2300-volt vertical machines. It was decided in this case to use the more usual scheme of self-synchronizing to put the machines on the line. For this reason they were provided with damper windings (these being unnecessary, of course, in the case of Johnson Falls) and a speed switch which operates to close the machine breaker at 95 per cent speed connecting it to the line without field, the field being applied by means of an auxiliary switch on the breaker. Another departure from the practise at Johnson Falls was the use of a vibrating regulator for each machine rather than a rheostatic regulator.

A very interesting picture of the characteristics of the two schemes of starting can be obtained from oscillographs taken at the time of closing the generator breaker. Fig. 6 shows the self-synchronizing generator.

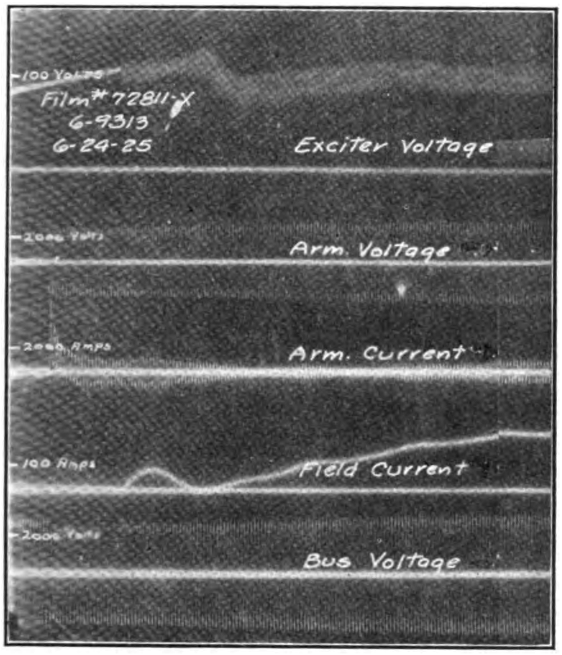

Fig. 6—Oscillograph of Self-Synchronizing Generator

It will be seen that as there is only the reactance of the winding to limit the current, it rises to seven and one-half times full-load current. Several seconds elapse before it has dropped to full load. When the breaker closes, the voltage falls to 75 per cent of normal for a few cycles. Fig. 7 shows the action with an automatic synchronizer. The armature current reaches only 35 per cent of full load and oscillates for a few seconds.

In deciding on the type of control to be used in the latest plant at Sandstone Rapids, experience obtained from the other two pointed to the use of an automatic synchronizer and the face plate rheostatic regulator. Here there are two 2400-kv-a., 6600-volt, 150-rev. per min. machines with direct-connected exciters. In general, the equipment will be very similar to Johnson Falls.

An interesting point in connection with these stations is that they are arranged for starting, not only from the supervisory control, but also from a low-frequency relay. This relay will energize the master element if the frequency drops to 57 cycles; a delay of a few seconds being provided to take care of momentary dips. Only one relay per station is necessary and after it starts machine No. 1, it is transferred to No. 2 to be ready to start it when required. The machines close down when a predetermined underload exists for a stated time, variable up to 30 min.; shutting-down takes place in the reverse order from starting up.

In order to show the extreme flexibility of this type of supervisory control it might be well to enumerate the number of different operations that can be performed by its means in the Sandstone Rapids Plant.

1. Start machine No. 1
2. Stop machine No. 1
3. Release lock out on machine No. 1. This is to allow the machine to operate as a complete automatic station starting by means of its frequency relay if conditions demand.
4. Supervise water-level machine No. 1
5. Supervise gate-opening machine No. 1
6. Increase load on machine No. 1
7. Decrease load on machine No. 1
8. Raise upper limit of gate-opening machine No. 1
9. Lower upper limit of gate-opening machine No. 1
10. Close breaker No. 1. This is a high-tension oil circuit breaker connecting to one of the 66,000-volt feeders.
11. Open breaker No. 1
12. Supervise breaker No. 1
13. Start machine No. 2
14. Stop machine No. 2
15. Release lock out on machine No. 2
16. Supervise water-level machine No. 2
17. Supervise gate opening machine No. 2
18. Increase load on machine No. 2
19. Decrease load on machine No. 2
20. Raise upper limit of gate-opening machine No. 2
21. Lower upper limit of gate-opening machine No. 2
22. Close breaker No. 2
23. Open breaker No. 2
24. Supervise breaker No. 2

Application to Old Stations

Automatic operation shows such economy that it is not only applied to new stations, but also many old ones are being changed over by the addition of the necessary equipment. In one station just put in operation under supervisory control, there is one 1000-kw., 100-rev. per min., 2300-volts, waterwheel generator and one 500-kw., 120-rev. per min., 2300-volt generator both excited from a 50-kw., 125-volt, 500-rev. per min. waterwheel-driven exciter. In general a direct-connected exciter is by far the more desirable for automatic control but, of course, in an old station it cannot always be provided.

Since the machines had no damper windings, they could not be expected to pull into step by the usual self synchronizing method and an automatic synchronizer was, therefore, provided. The station is operated by

supervisory control from a point two miles away. No voltage regulator is used as the machines operate with fixed excitation. The first operation is to start up the exciter and when it is up to voltage machine No. 1 or No. 2 is brought up to speed and field applied. As it nears synchronism, the automatic synchronizer is connected in circuit and the machine synchronized to the line. Only one synchronizer is provided for the two machines and it is automatically connected to the incoming machine as it speeds up.

In addition to the control and supervision of the generators proper, there are 9-feeder circuit breakers in the station which are operated over the supervisory equipment.

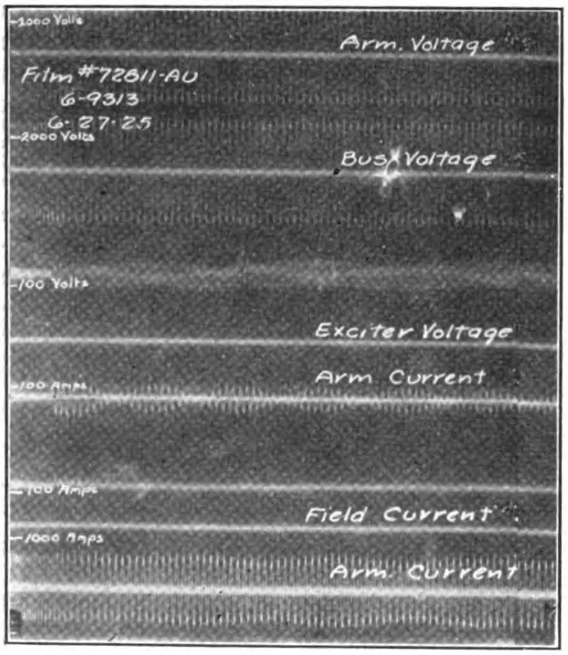

Fig. 7—Oscillograph of Generator Automatic Synchronizing

Large Automatic Unit

One of the largest automatic generators to be put in service will be that of the New England Power Company rated at 9000-kv-a., 2300-volts, three-phase, 60-cycle, 180-rev. per min. with direct connected exciter. The equipment is entirely automatic and in general follows along the usual lines. The machine is started by a combination of time clock and the energizing of the high-tension line from the neighboring station of Davis Bridge, three mi. away. The generator will come into service when the high line is energized providing the time clock has completed contact. The latter can also be arranged to take the generator off and put it on again over the noon hour.

The machine is provided with damper windings and comes on the line by the self-synchronizing method. Remote control is provided from Davis Bridge for adjusting the load on the governor motor when desired but there is nothing further in the way of supervision. As the automatic unit will be on the stub end of a line, the output can be measured at Davis Bridge by the incoming meters.

The voltage is stepped up from 2300- to 110,000-volts through three 2000-kv-a. transformers to tie in with the power system. An emergency motor generator set is provided for excitation in case of trouble with the direct-connected exciter.

Synchronous Visual Type Supervisory Control

In all these installations, the same kind of supervisory control has been used—the audible type—because it is quite sufficient to take care of all requirements. It is possible, however, that what is known as the Synchronous Relay Type of control will find application where remote synchronizing is desirable or where there are such a large number of stations to be controlled that a constant visual indication is required of the status of the equipment in each one.

This apparatus is extremely flexible in its application and there is practically no limit to the number or kinds of operations that can be performed. It does not operate on the impulse or code principle but really sets up a complete circuit from the dispatchers board key over two line wires to the control relay of the apparatus to be operated. This can be a circuit breaker or any indicating device such as a float switch, ammeter or voltmeter which can be arranged to reproduce its indication at the dispatching point.

The apparatus consists of batteries of relays at both ends of the line; these operate in synchronism and are kept together over a two-wire drive circuit with interlocks so arranged that the relays must operate in a predetermined order and corresponding relays at both ends of the line must operate together otherwise the whole equipment comes to rest and refuses to function. Each pair of relays corresponds to some particular operation in the automatic station and as they operate they step another two wire signal line from point to point so that at any particular instant a complete circuit is provided over these signal wires from the control key in the dispatcher's office to the proper apparatus in the automatic station.

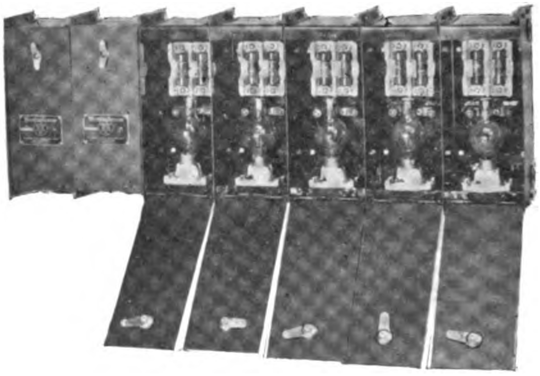

Fig. 8—Supervisory Control Protective Tubes

When it is desired to perform any particular opera-

tion, the corresponding key is depressed and then the drive circuit set in operation. The relays operate in synchronism until the signal circuit reaches the key that has been operated and thus a complete circuit has been completed through to the apparatus and the operation takes place. In the case of remote synchronizing, voltage transformers are connected to points in the substation cabinet and a synchroscope to corresponding points at the dispatcher's end. The circuit breaker to be closed is arranged to be the next point in sequence so that, the moment synchronism is reached, the dispatcher operates a key which instantly transfers the signal line from the synchroscope point to the breaker point and closes the breaker.

Continuous lamp indication is given of the position of all equipment and telltale lights are provided to show any automatic operation.

Supervisory Protective Equipment

It might be well to mention here the necessity for some kind of apparatus to protect the supervisory control equipment from line disturbances. It is very common to find the telephone wires used for the supervisory run underneath the high-tension transmission lines where they will be subject to induced voltages from the high-tension line as well as the possibility of direct contact. In order to prevent such over-voltages getting into the control equipment vacuum tubes to provide a path to ground are connected to the supervisory line at both ends. Fig. 8 shows a battery of such tubes. Each tube contains four electrodes. In the case of a two-wire line, an electrode is connected to each line and the other two are connected together and to ground. The four are spaced so that they will discharge at a difference of potential of about 250 volts between pairs, thus preventing any higher voltage than this remaining on the control wires. Small fuses are furnished for connection between the tubes and the supervisory and in the case of overhead wires paralleling high-tension lines, fuses of the transmission line voltage rating are also used on the line side. These vacuum tube protectors have been known to take care of the most severe conditions without difficulty.

D-C. Hydro Station. Although the great majority of installations are for a-c. generators there are some cases where vertical d-c. machines have been used. These are provided with the necessary WR^2 and overspeed capacity and use Kingsbury thrust bearings. The commutator is placed below the rotor to prevent carbon and copper falling in the windings.

The machines are entirely automatic in operation, being controlled by a float switch. As the water-level rises the float makes contact and starts the governor oil pump motor and when the proper operating pressure has been reached, an electric solenoid puts the governor in operation, the gates open and the machine comes up to speed. The automatic voltage regulator then comes into operation and balances the voltage of the machine with the bus by working on a motor-operated field rheostat. The main d-c. breakers are closed and the load taken by the generator is regulated by the water-level; the float switch operates over a rheostat which is inserted in the voltage regulator circuit thus recalibrating it and allowing it to regulate for higher or lower voltage and therefore larger or smaller output. The units are shut down at a predetermined minimum head.

In addition to balancing the voltage at start and regulating it for load the regulator has a third element which limits the output of the generator in case of trouble. In event of overload, the voltage is cut down thus limiting the output and if the overload continues the thermal relays lock the machine out.

Conclusion

While no attempt has been made to go into the equipment supplied for any of these plants in very great detail, it is hoped that sufficient has been described to show the variety of applications confronting the automatic engineer, the types of problems that are encountered, and the extreme flexibility of the equipment in its capacity to take care of practically any conditions that can arise.

ELECTRICAL HOUSEHOLD APPLIANCES IN THE NETHERLANDS

A large demand for modern electrical household appliances has recently been created in the Netherlands as a result of the activities of the municipal electric works at Amsterdam where American products are generally favored.

The general application of electrical appliances has been restricted by the comparatively high rates, consequently the number of electric household appliances used has been small. Special rates are now being quoted for electricity used during the daytime, and the municipal electric works at Amsterdam has announced that it will supply electric energy at a lower "night tariff" from 11 p. m. to 7.30 a. m.

The municipal enterprise is demonstrating devices in a special showroom. Among the articles shown is an electric stove which stores heat during the night hours for use the next day. When the stove, which weighs about 330 lbs. is fully charged, the inside temperature is 275 deg. cent., while the outside is 70 deg. cent.

Various types of electrically operated refrigerators are also on exhibition. Water tanks with a capacity of 1½, 6, 10, 40, and 60 gallons are available. The water is heated to 85 deg. cent. Radiation is at the rate of three-quarters of a degree per hour, so that hot water will be available all day.

The municipal works are supplying purified, dry air in cylinders which can be placed in bedrooms of people suffering from asthma.

Abridgment of

Synchronous Machines

I—An Extension of Blondel's Two-Reaction Theory

BY R. E. DOHERTY[1] and C. A. NICKLE[1]

Associate, A. I. E. E. Associate, A. I. E. E.

***Synopsis.**—Blondel treated salient pole machines by resolving the fundamental space component of m. m. f. along the two axes of symmetry—the direct axis of the pole, and the quadrature axis between poles. Using this idea and applying harmonic analysis, Blondel's theory has been extended in the present paper to a comprehensive system of treatment in which the effect of harmonic m. m. fs., as well as the fundamental and also of field m. m. f. in the quadrature axis, as well as in the direct have been taken into account.*

It is shown that the "armature leakage flux" which causes reactance voltage drop in synchronous operation comprises all fluxes due to armature currents which generate fundamental voltage except the space fundamental component, the latter constituting the total flux of "armature reaction."

Impressing upon the variable air-gap permeance those space harmonics of m. m. f. which are due to the fundamental time component of current and which therefore rotate at various fractional speeds produces odd space harmonics of flux rotating at many different speeds and in opposite directions. Some of these listed in Table I produce fundamental voltage, but most of them generate time harmonics. The former, which are reactive voltages, are only those of the nth space order rotating at one nth speed—that is, those which correspond in space order and speed to the harmonic m. m. fs. The corresponding reactances are definitely defined in Appendix C in terms of permeance coefficients, and means are outlined for quantitative determination of such coefficients from graphically constructed field plots. Although, strictly, there are as many field plots required as there are significant m. m. f. harmonics, an approximation, developed in Appendix B, is given in which only one plot is necessary, other permeance waves being derived therefrom.

It is shown that only the average term and the second space harmonic of the permeance series affect the fundamental voltage. Hence, unless it is required to calculate the harmonic voltages, only those two terms of the permeance series need to be determined.

In the application of the results, the fundamental voltages thus produced by the armature currents are superposed upon that due to current in the field winding, which latter has been previously treated. This gives the vector diagram, Fig. 19, from which the steady state relations are set down in equations.

In Part II, the steady-state angle-power relations are developed, including an interpretation of the "reluctance term" in the power or torque equation.

In Appendix D, the vector diagram for salient pole machines is interpreted in terms of the well-known Potier diagram for cylindrical rotor machines. Also the effect of saturation both on angle-power relation and on the value of excitation required under load, is discussed.

Subsequent papers in the near future will present results which have been obtained from the application of the method and point of view here outlined to the solution of problems relating to abnormal operating conditions of synchronous machines.

* * * * *

INTRODUCTORY

THE ever widening application of synchronous machines and their great importance as a factor in the operation of power systems have created the occasion for an extended study of their behavior under the various normal and abnormal conditions. The results of the investigation comprise not only the determination of such operating characteristics, but also extensions in fundamental theory and in mathematical facilities for applying it. It is the authors' purpose to present the results of the investigation in a series of papers, the present one dealing with the theory relating to steady-state, polyphase operation.

The present work is essentially an extension of Blondel's[2] treatment, and an application of the results to definite problems. His fundamental conception of resolving the armature m. m. fs. and fluxes in salient pole machines into two space components—one in line with the pole axis, the other in quadrature thereto—is the basis of the present study. The fundamental premises are extended, and new constants which are necessary to characterize the performance are defined and incorporated in the equations. As in any engineering analysis, this has involved certain assumptions, carefully defined, which would simplify the equations to a practical degree, but which would not throw the calculated results beyond the limit of reasonable accuracy. That is, the predominating factors which practically determine the characteristics have been included, and those have been omitted which complicate the equations without significantly affecting the calculated result. The final equations are thus relatively simple, considering the nature of the phenomena related.

Lyon[3] has treated the *flux* distribution, voltage and power of a synchronous machine by an interesting application of harmonic analysis to the flux waves which must exist. He starts with a general equation for the complicated resultant flux wave; hence, the resulting series contain coefficients which it would be very difficult to determine. However, it is true, as Prof. Lyons says, that it is "useful to know what harmonics may be present even when their magnitudes can not be calculated." The present paper, while applying the same general method of attack, *i. e.*, harmonic analysis, nevertheless starts with the resolution of *m. m. f.* waves, instead of *flux* waves, and takes advantage of the symmetry embodied in salient pole

3. Bibliography 7.

machines, by making the resolutions along the two axes of symmetry,—*i. e.*, applies Blondel's idea. This treatment gives m. m. f. waves spread over definite permeance distributions, thus making it possible to determine the coefficients of the significant harmonics of the flux waves.

Thus several aspects of the problem have been treated during the investigation; an extension in fundamental theory, comprising an harmonic analysis of the phenomena in the air-gap, and the inclusion of exciting field ampere-turns in the quadrature axis, the definition of characteristic constants, and thus, to this extent, a basis for their determination; the formulation of characteristic equations; the excitation-voltage-load characteristic; angle-power relations under steady and transient states; short-circuit phenomena under steady and transient states, single phase and polyphase; and mechanical forces and torques due to electromagnetic reactions under various conditions.

The present paper is in two parts. The first interprets and extends the theory relating to steady-state conditions, including definitions of the essential constants; constructs the excitation-voltage-load diagram, and shows the relation of this to the corresponding familiar diagram for cylindrical rotor construction. Part II treats the steady-state power-angle relations.

I. General Theory

Percentage Representation of Quantities. It is convenient to express the quantities involved in percentage (as a fraction) of their normal values. While the base of the fraction for each quantity has definite dimensions, the fraction is, of course, a numeric, and its use avoids cumbersome conversion factors in the equations. Nevertheless, the results thus expressed by fewer symbols are none the less definite. It is believed that many mathematical treatments of engineering problems could be immensely simplified in this way.

On this basis:

Unit voltage is normal rated voltage.

Unit armature current is normal rated current.

Unit power is normal three-phase power.

Unit impedance is that impedance through which normal voltage at normal frequency causes normal current to flow.

Unit field current is that field current which induces normal fundamental, open circuit voltage at normal speed.

Unit space fundamental flux is the flux which rotating at normal speed induces unit voltage.

Unit flux density is the maximum density of the unit fundamental flux wave.

Unit space fundamental magnetomotive force is the resultant fundamental magnetomotive force produced by normal three-phase armature current.

Unit permeance coefficient is that coefficient which, multiplied by unit m. m. f., gives unit flux density.

Unit time is the time required for one cycle of fundamental frequency.

Unit angle is 2π.

Unit speed is normal synchronous speed.

All armature voltages and currents are per phase.

Armature Current Phenomena. It has been shown by Arnold and others[4] that in a synchronous machine, the *space* distribution of *m. m. f.* due to each armature coil can, under certain reasonable assumptions[5], be resolved into rotating space harmonics. The superposition of these m. m. f. distributions due to all coils produces an interesting and highly convenient result—namely, a number of space sinusoids of m. m. f. of different pole spans, rotating at different speeds, some forward, some backward. Thus, for instance, in a balanced three-phase system, the fundamental sinusoid alone rotates at synchronous speed with respect to the armature, *i. e.*, with the field poles; the third harmonic, vanishes; the fifth, with a pole span of one-fifth, rotates backward at one-fifth of synchronous speed; the seventh, with a one-seventh span, forward at one-seventh speed; the ninth vanishes; the 11th, backward, and so on. Stated in other words, for balanced current (sine wave in time) in a three-phase armature, there are a number of different, independent, *space* sinusoids of *m. m. f.*, each rotating at a different speed; and they exist as sinusoids, of course, regardless of the salient-pole character of the magnetic circuit of the rotor, so long as the poles are symmetrical. Fig. 1 shows the fundamental and fifth of such a system at one instant of time.

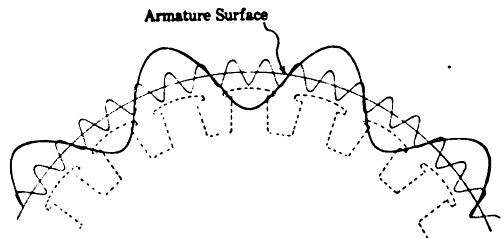

FIG. 1—TRAVELING SPACE SINUSOIDS OF M. M. F.

While the method is here discussed in terms of a three-phase machine, the general theory obviously applies to any polyphase system. In two-phase, the only difference is in the number of harmonics dealt with. For this case, the space harmonics of m. m. f. are as follows; the fundamental, forward at synchronous speed, the 3rd backward at $1/3$ speed, 5th forward at $1/5$ speed, etc.—all of which may be treated in the foregoing manner. In single-phase, the method of analysis is the same, but the results involve some additional

4. Bibliography 2; and 4, chapter VII.

5. The particular assumptions involved in order that m. m. f. with respect to the rotor may be definite at each point of the armature surface are infinite permeability of the armature iron, no slots, armature current concentrated at points along the armature surface, and symmetrical field structure.

Subject to these assumptions, the armature m. m. f. becomes equivalent to a distribution of magnetic potential along the armature surface.

constants which enter the problems of transient state; hence this case will be treated in a later paper.

If there are time harmonics in the current, each one of them will produce its own system of space sinusoids of m. m. f., which will be like that produced by the fundamental term in all respects except that the speed of rotation of each sinusoid will be increased by the order of the time harmonic of current. For instance, if the current in each phase comprises a fundamental and a fifth harmonic, there will be two systems of space sinusoids: one due to the fundamental, as described in the foregoing paragraph; and another in which the sinusoids of full pole span (*i. e.*, fundamental in space) rotates at five times synchronous speed, the third vanishes, the fifth (one-fifth pole span) at five-fifths speed, and so on.

It is possible to superpose the armature m. m. fs.[6] as in the foregoing, because they are all assumed[7] to be distributed along the armature surface. However, the field pole m. m. f. is not. It is distributed radially and at some distance from the armature currents. Hence, the superposition of the armature and field m. m. fs. is not permissible. But all of the *fluxes* at any point on the armature surface, produced by all of these m. m. fs., can be superposed; likewise, the corresponding voltages.

So the problem is to determine all of the space harmonics of flux which are produced by all currents of both the field and armature, and which generate voltage in the armature conductors; then to superpose such of them as are significant, in order to determine the resultant voltage. In addition, there are voltages due to those fluxes which do not appear in the air-gap—namely, slot leakage and end-winding leakage. These fluxes are practically proportional to, and in phase with, the armature current, and thus produce corresponding reactive voltages. The resultant of all of the foregoing voltages is, of course, the terminal voltage.

Turn now to the flux waves produced by the rotating sinusoids of m. m. f. Under steady-state operation the fundamental space wave of the armature m. m. f. rotates at synchronous speed with the field poles, at some definite angle of displacement. Hence whatever may be the shape of the flux wave thus produced, it is nevertheless steady in value and fixed with respect to the poles. All of the space harmonics of m. m. f., on the contrary, rotate at speeds different from synchronous speed, and therefore travel over magnetic paths of varying permeance, each wave of m. m. f. producing a pulsating, tufting, rotating flux—rotating, as it were, at a non-uniform velocity with respect to the poles, yet, at the same time, pulsating in magnitude.

6. Neglecting the magnetic reluctance of the armature.

7. The assumption is that the m. m. f. wave of each coil is approximately a square wave, and hence that the total current in each slot is concentrated in a conductor in the center line of the slot, at the surface of the armature, as illustrated for a particular case in Fig. 2.

This is, of course, a complicated phenomenon, but it can be handled analytically as follows:

1. Resolve each rotating space harmonic of m. m. f. into two stationary pulsating waves with respect to the poles.
2. Determine the two corresponding stationary (with respect to the poles), pulsating *flux* waves produced by (1).
3. Combine the flux waves of (2) into *rotating* space harmonics of flux.
4. Determine the component voltages which the space harmonics of flux in (3) generate.

The same method of analysis, of course, applies to the space fundamental of m. m. f. as well as to the space harmonics of m. m. f., the essential difference in result being that the speed of the space harmonics of *flux* due to the space fundamental of m. m. f. is zero with respect to the poles.

Before proceeding to such analysis, it is necessary to resolve the system of three-phase, balanced, sine-wave (in time) currents into two component three-phase systems: one in which the current in each individual phase reaches maximum at the instant the axis of the field pole coincides with the axis of magnetization of the

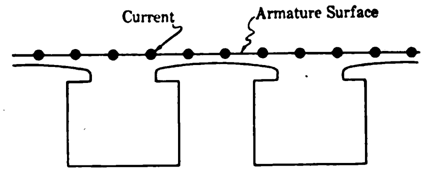

FIG. 2—ASSUMED CURRENT DISTRIBUTION ALONG THE ARMATURE SURFACE

phase under consideration—this is called the *direct* component because it produces the direct component of armature reaction; and another in which the current in each individual phase reaches maximum at the instant its axis of magnetization is in line with the axis midway between poles, that is, one-quarter cycle later—this is the *quadrature* component. Each of these complementary, three-phase systems has its own set of rotating space sinusoids of m. m. f. as described in the foregoing.

While the general case is treated in Appendix A, the physical significance is necessarily somewhat obscured in such a treatment. Hence it appears desirable to illustrate by carrying through the analysis of some particular harmonic,—say the fifth. The procedure is the same for any harmonic, including the fundamental.

The first step is to define the references clearly. Since the resolution of m. m. fs. is to be made with respect to the poles, the space reference will be taken as the axis of a field pole, and time will be reckoned from the instant the axis of magnetization of some particular phase, say phase 1, lines up with the pole axis. Thus, referring to Fig. 3A, the electrical angle α is measured from the axis of pole a in the direction of rotation. The position of the axis of phase 1 with reference to pole a is shown for the instant $t = 0$. In

Fig. 3B, the position of phase 1 with respect to pole a is shown for

$$t = 0.25, \text{ for which } \alpha = -0.25$$

Now consider the time-space relations of the m. m. f. waves. By hypothesis the *direct* component of current is maximum at the instant for which the space relations of the m. m. fs. are shown in Fig. 3A, that is at $t = 0$. That is, the instantaneous value of this current is

$$i_d \cos t \qquad (1)$$

Thus at that moment, the fundamental[8] A_{1d} and the fifth A_{5d} space harmonics of m. m. f. have the space relations with respect to the poles as shown. Be it remembered that the fundamental is fixed in magnitude and position with respect to the pole, whereas the 5th, like the other harmonics, is rotating with respect to the pole.

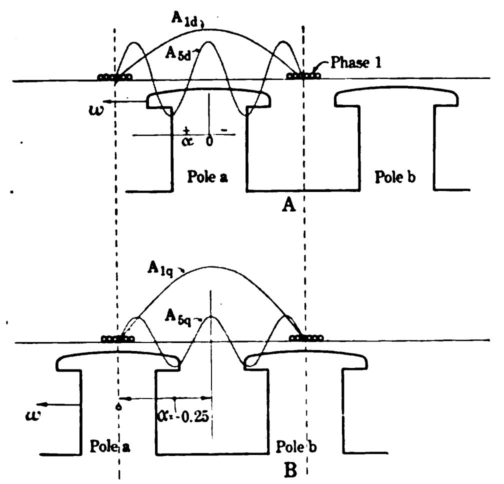

FIG. 3—SPACE AND TIME RELATIONS BETWEEN THE FUNDAMENTAL AND 5TH SPACE HARMONIC OF M. M. F.

A—For direct component of armature current
B—For quadrature component of armature current

The *quadrature* component of current, on the other hand, is a maximum at a *later* time, that is at $t = 0.25$. Thus the instantaneous value is

$$i_q \sin t \qquad (2)$$

and the space relations of its corresponding m. m. f. waves *at that instant* are shown in Fig. 3B. But obviously this position is *not the space position which the 5th had at* $t = 0$, since the wave is rotating with respect to the poles. The *quadrature* fundamental, like the *direct* fundamental, is of course stationary with respect to the pole, and of constant magnitude.

To analyze the 5th, it is necessary to obtain an expression for each of the two components of the rotating 5th space sinusoid of m. m. f., namely a_{5d} and a_{5q}. The known characteristics are (a) the amplitude, (b) the space distribution, or position of the rotating wave at one instant, and (c) the speed and direction of rotation. Take the *direct* component first:

(a) amplitude, A_{5d}

(b) maximum value of wave coincides with pole axis at $t = 0$

(c) rotates backward with respect to the armature at $^1/_5$ speed, and with respect to the poles at $^6/_5$ speed, thus at an electrical angular velocity (referred to its own wave length) of six times normal.

The equation for such a rotating wave is

$$a_{5d} = A_{5d} \cos \{ 5 (\alpha + \psi) + 6 t \} \qquad (3)$$

at $t = 0$, it is,

$$A_{5d} \cos 5 (\alpha + \psi)$$

But from the assumed boundary condition in Fig. 3A, the space distribution at $t = 0$ is

$$A_{5d} \cos 5 \alpha$$

Hence $\psi = 0$. Thus the wave is

$$a_{5d} = A_{5d} \cos (5 \alpha + 6 t) \qquad (4)$$

Likewise, the 5th rotating m. m. f. wave due to the *quadrature* component of current is

$$a_{5q} = A_{5q} \cos \{ 5 (\alpha + \psi') + 6 t \} \qquad (5)$$

At $t = 0.25$, it is

$$A_{5q} \cos \{ 5 (\alpha + \psi') + 1.5 \}$$

which must represent the wave in the particular position shown in Fig. 3B, that is

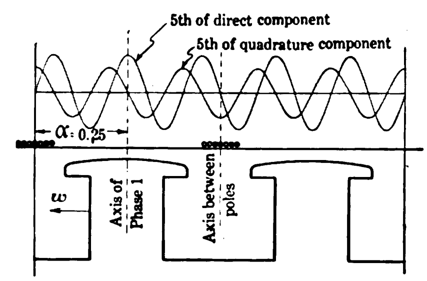

FIG. 4—THE DIRECT AND QUADRATURE COMPONENTS OF THE 5TH SPACE HARMONIC OF M. M. F. AT $t = 0$. EQS. (2) AND (4) RESPECTIVELY

$$- A_{5q} \sin 5 \alpha$$

Thus

$$\cos \{ 5 (\alpha + \psi') + 1.5 \} = - \sin 5 \alpha$$

Hence

$$\psi' = - .05$$

and the equation of the wave is, by (5)

$$a_{5q} = A_{5q} \cos \{ 5 (\alpha - .05) + 6 t \}$$

or

$$a_{5q} = A_{5q} \sin (5 \alpha + 6 t) \qquad (6)$$

The waves represented by (4) and (6) are shown in Fig. 4 for the instant $t = 0$.

The stated plan is to resolve each of the two waves (4) and (6) in two pulsating components, stationary with respect to the poles, and then determine the corresponding stationary, pulsating flux waves. Thus, by direct trigonometric transformation, (4) becomes,

$$a_{5d} = A_{5d} (\cos 5 \alpha \cos 6 t - \sin 5 \alpha\, 6 t)$$

8. The waves as shown are due not only to current in phase 1, but also to currents in the other two phases, the resultant waves of all the currents having, *at that instant*, the same space distribution as the corresponding harmonics produced by phase 1 alone. The magnitudes are different, of course.

which comprises the two stationary pulsating waves

$$a'_{5d} = A_{5d} \cos 5\,\alpha \cos 6\,t \quad (7)$$

and

$$a''_{5d} = -\,A_{5d} \sin 5\,\alpha \sin 6\,t \quad (8)$$

Similarly, (6) becomes,

$$a'_{5q} = A_{5q} \sin 5\,\alpha \cos 6\,t \quad (9)$$

and

$$a''_{5q} = A_{5q} \cos 5\,\alpha \sin 6\,t \quad (10)$$

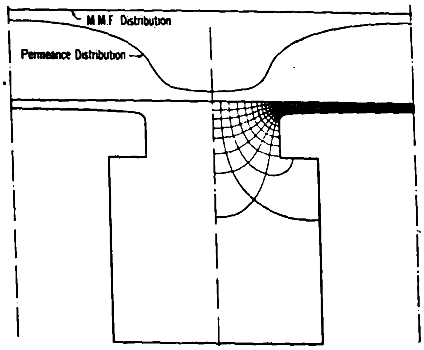

FIG. 5—A—FLUX AND PERMEANCE DISTRIBUTION FOR THE ZERO HARMONIC (CONSTANT M. M. F.), GRAPHICALLY DETERMINED

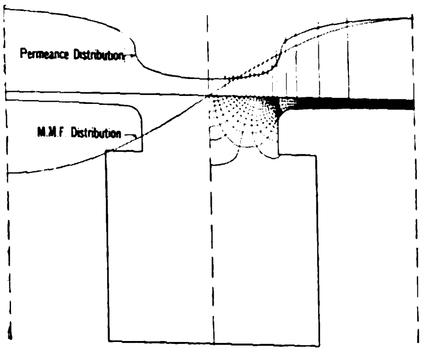
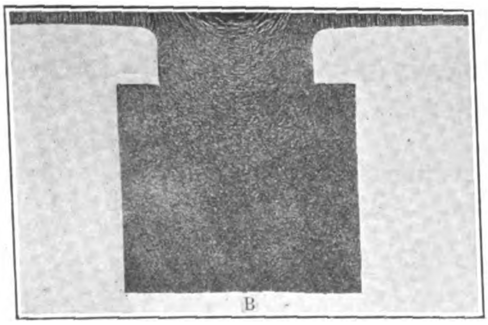


A

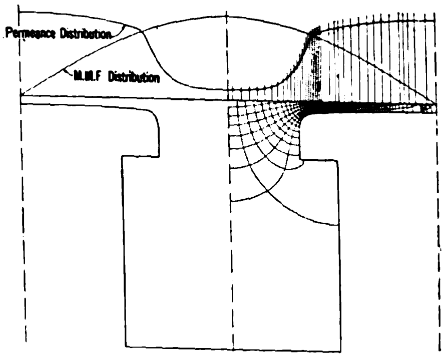
FIG. 6—A—FLUX AND PERMEANCE DISTRIBUTION FOR FUNDAMENTAL, COS α DISTRIBUTION OF M. M. F., GRAPHICALLY DETERMINED



B—FLUX DISTRIBUTION BY TEST

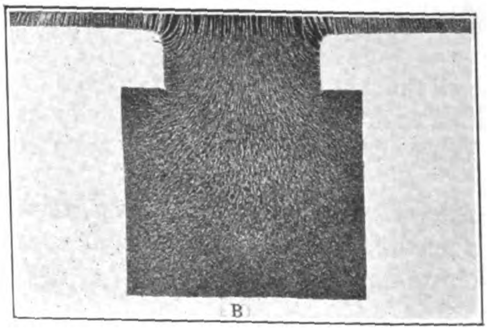
The next step is to obtain the flux waves produced by these stationary, pulsating waves of m. m. f. The product of the m. m. f. at any point along the armature, by the permeance coefficient applying to the magnetic path at that point, gives the flux density at that point. But the permeance[9] coefficient, as well as the m. m. f., is a function of the space angle α. Although it is different for each harmonic and is in any case a somewhat complicated function of α, it is at least a function which is symmetrical about both the direct and quadrature axes, in all cases of symmetrical salient poles, and can therefore be represented by a Fourier series of even cosines.[10] Fig. 5 shows the distribution of m. m. f., permeance coefficient and resultant flux for the zero harmonic; Fig. 6, the same for the fundamental, cos α distribution of m. m. f.; Fig. 7, for fundamental, sin α distribution of m. m. f.; Fig. 8, for the 5th harmonic, cos $5\,\alpha$ distribution of m. m. f.

These flux distributions were determined in one case



A

FIG. 7—A—SAME AS FIG. 6, EXCEPT FOR SIN α DISTRIBUTION OF M. M. F.



B—FLUX DISTRIBUTION BY TEST

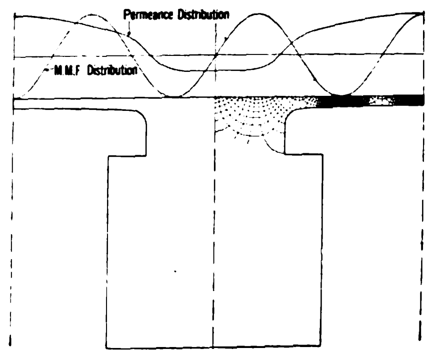
by graphic method, and in the other by test. Also the permeance distributions were determined in one case from the field plot, and in the other, from the curve in

9. Question may be raised whether it is proper to consider the m. m. f. and permeance thus distributed, since the air-gap, in the case of salient poles, is extremely variable, and hence the total m. m. f. indicated at any point may not be entirely consumed in the corresponding permeance; that is, the return path from pole to armature may consume more or less than the path from armature to pole. It is permissible because, over a pole pitch, the distributions are symmetrical, thus giving a corresponding return path in a similar position somewhere within the pole pitch.

10. Even cosines, because a cycle of the resultant permeance wave is of one-pole pitch, thus one-half cycle of fundamental space angle.

Fig. 10, derived in Appendix B. It will be noted that there is a very reasonable agreement. By appropriate modification of the result for uniform air-gap, the permeance distribution for salient poles may be plotted, as in Figs. 11 and 12, and analyzed.

The two permeance coefficient series, one for the



A

B—FLUX DISTRIBUTION BY TEST

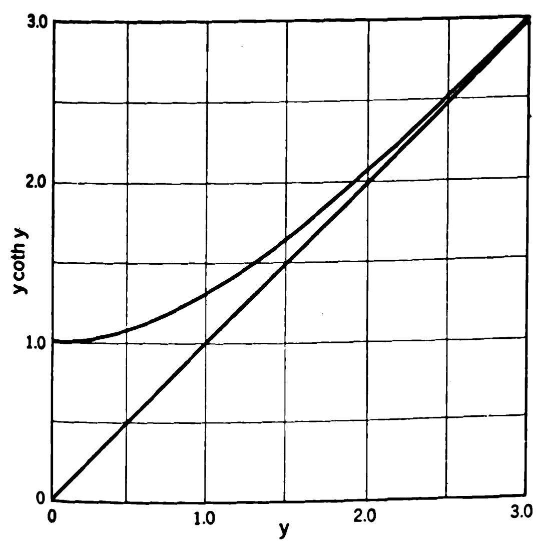

FIG. 10

cosine, the other for the sine distribution of the 5th harmonic m. m. f., are respectively,

$$p^{\mathrm{V}}_{c} = p^{\mathrm{V}}_{0c} + p^{\mathrm{V}}_{2c} \cos 2\,\alpha + p^{\mathrm{V}}_{4c} \cos 4\,\alpha + \ldots \quad (11)$$

and

$$p^{\mathrm{V}}_{s} = p^{\mathrm{V}}_{0s} + p^{\mathrm{V}}_{2s} \cos 2\,\alpha + p^{\mathrm{V}}_{4s} \cos 4\,\alpha + \ldots \quad (12)$$

the subscript c and s indicating cosine and sine respectively, and the numerally (thus avoiding the appearance

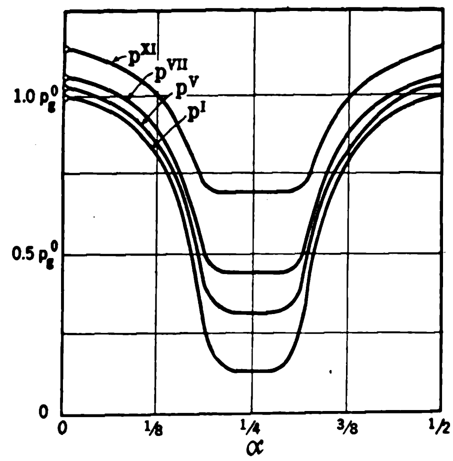

FIG. 11—PERMEANCE DISTRIBUTIONS DETERMINED FROM FIGS 21 AND 22

ANALYSIS OF THESE WAVES GIVES:

$p_0^{\mathrm{I}} = 0.66\ p_g^0$	$p_2^{\mathrm{I}} = 0.44\ p_g^0$
$p_0^{\mathrm{V}} = 0.73\ p_g^0$	$p_2^{\mathrm{V}} = 0.37\ p_g^0$
$p_0^{\mathrm{VII}} = 0.79\ p_g^0$	$p_2^{\mathrm{VII}} = 0.33\ p_g^0$
$p_0^{\mathrm{XI}} = 0.94\ p_g^0$	$p_2^{\mathrm{XI}} = 0.25\ p_g^0$

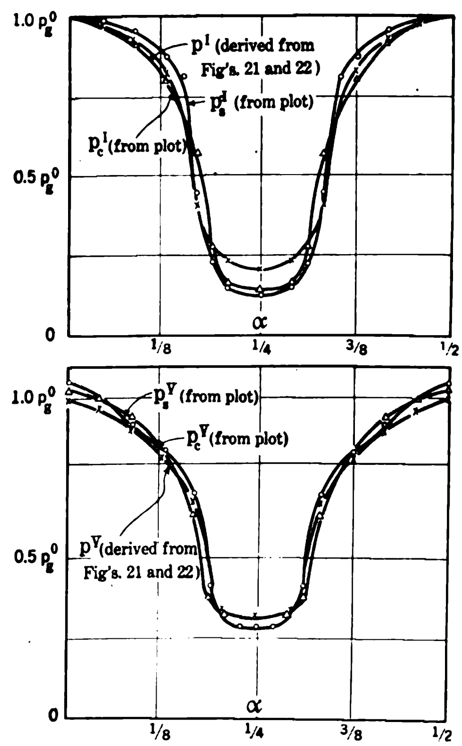

FIG. 12—COMPARISON OF DERIVED AND PLOTTED PERMEANCES FOR 1ST AND 5TH HARMONICS

of an exponent) indicating that the series is for the 5th space harmonic of m. m. f.

The flux waves are, therefore, obtained by multiplying (7) and (10) by (11), and (8) and (9) by (12).

Thus,

$$\beta'_{5d} = \frac{1}{2} A_{5d}[(p^{\mathrm{V}}_{4c} + p^{\mathrm{V}}_{6c}) \cos \alpha + (p^{\mathrm{V}}_{2c} + p^{\mathrm{V}}_{8c}) \cos \overset{3}{2} \alpha$$
$$+ (2\, p^{\mathrm{V}}_{0c} + p^{\mathrm{V}}_{10c}) \cos 5\alpha$$
$$+ (p^{\mathrm{V}}_{2c} + p^{\mathrm{V}}_{12c}) \cos 7\alpha + \ldots] \cos 6t \qquad (17)$$

$$\beta''_{5d} = -\frac{1}{2} A_{5d}[(p^{\mathrm{V}}_{4s} - p^{\mathrm{V}}_{6s}) \sin \alpha + (p^{\mathrm{V}}_{2s} - p^{\mathrm{V}}_{8s}) \sin 3\alpha$$
$$+ (2\, p^{\mathrm{V}}_{0s} - p^{\mathrm{V}}_{10s}) \sin 5\alpha$$
$$+ (p^{\mathrm{V}}_{2s} - p^{\mathrm{V}}_{12s}) \sin 7\alpha + \ldots] \sin 6t \qquad (18)$$

$$\beta'_{5q} = \frac{1}{2} A_{5q}[(p^{\mathrm{V}}_{4s} - p^{\mathrm{V}}_{6s}) \sin \alpha + (p^{\mathrm{V}}_{2s} - p^{\mathrm{V}}_{8s}) \sin 3\alpha$$
$$+ (2\, p^{\mathrm{V}}_{0s} - p^{\mathrm{V}}_{10s}) \sin 5\alpha$$
$$+ (p^{\mathrm{V}}_{2s} - p^{\mathrm{V}}_{12s}) \sin 7\alpha + \ldots] \cos 6t \qquad (19)$$

$$\beta''_{5q} = \frac{1}{2} A_{5q}[(p^{\mathrm{V}}_{4c} + p^{\mathrm{V}}_{6c}) \cos \alpha + (p^{\mathrm{V}}_{2c} + p^{\mathrm{V}}_{8c}) \cos 3\alpha$$
$$+ (2\, p^{\mathrm{V}}_{0c} + p^{\mathrm{V}}_{10c}) \cos 5\alpha$$
$$+ (p^{\mathrm{V}}_{2c} + p^{\mathrm{V}}_{12c}) \cos 7\alpha + \ldots] \sin 6t \qquad (20)$$

Thus the stationary pulsating 5th space harmonic of m. m. f. a'_{5d}, impressed on the variable (in space) permeance, produces space waves of *flux* of *all* odd harmonics, including the fundamental, there being a definite progression in the subscripts of the permeance constants for the increasing order of the odd space harmonic.

It will be noted that if the corresponding harmonics of (**17**) and (**18**), and of (**19**) and (**20**) be paired, the result will be that for each space harmonic of the series, there will be two flux waves in space and time quadrature, *but of different amplitude.* Now just as the rotating 5th harmonic m. m. f. wave was resolved into two equal stationary pulsating waves in space and time quadrature, so in the present case the equal components (*i. e.*, two amplitudes equal to the smaller) can be composed into one main rotating wave; and the difference between the amplitudes constitutes a residual, single, stationary, pulsating wave, which can be resolved, according to the well-known scheme, into two equal waves of one-half amplitude, rotating in opposite directions. Thus one of these must rotate with the foregoing main wave, and in space phase with it, and the other alone in the opposite direction.

Thus equations (**17**) and (**18**) together contain two rotating *flux* waves for each odd harmonic of space distribution, the speeds of rotation being different for all harmonics; hence a corresponding difference also in the magnitude and order of the harmonic voltages thus generated; likewise, (**19**) and (**20**). These flux waves are obtained by pairing the corresponding space harmonics of (**17**) and (**18**), and of (**19**) and (**20**), and expanding them.[11]

11. They could be obtained also by the scheme used to illustrate the physical meaning of the waves, as in Fig. 7.

Eqs. (**17**) and (**18**) therefore give:

$$\beta_{5d1} = \frac{1}{4} A_{5d}[(p^{\mathrm{V}}_{4s} - p^{\mathrm{V}}_{6s}) + (p^{\mathrm{V}}_{4c} + p^{\mathrm{V}}_{6c})] \cos(\alpha + 6t)$$
$$+ \frac{1}{4} A_{5d}[-(p^{\mathrm{V}}_{4s} - p^{\mathrm{V}}_{6s}) + (p^{\mathrm{V}}_{4c} + p^{\mathrm{V}}_{6c})] \cos(\alpha - 6t) \qquad (21)$$

$$\beta_{5d3} = \frac{1}{4} A_{5d}[(p^{\mathrm{V}}_{2s} - p^{\mathrm{V}}_{8s}) + (p^{\mathrm{V}}_{2c} + p^{\mathrm{V}}_{8c})] \cos(3\alpha + 6t)$$
$$+ \frac{1}{4} A_{5d}[-(p^{\mathrm{V}}_{2s} - p^{\mathrm{V}}_{8s}) + (p^{\mathrm{V}}_{2c} + p^{\mathrm{V}}_{8c})] \cos(3\alpha - 6t) \qquad (22)$$

$$\beta_{5d5} = \frac{1}{4} A_{5d}[(2\, p^{\mathrm{V}}_{0s} - p^{\mathrm{V}}_{10s})$$
$$+ (2\, p^{\mathrm{V}}_{0c} + p^{\mathrm{V}}_{10c})] \cos(5\alpha + 6t)$$
$$+ \frac{1}{4} A_{5d}[-(2\, p^{\mathrm{V}}_{0s} - p^{\mathrm{V}}_{10s})$$
$$+ (2\, p^{\mathrm{V}}_{0c} + p^{\mathrm{V}}_{10c})] \cos(5\alpha - 6t) \text{ etc.} \qquad (23)$$

And (**19**) and (**20**) give:

$$\beta_{5q1} = \frac{1}{4} A_{5q}[(p^{\mathrm{V}}_{4s} - p^{\mathrm{V}}_{6s}) + (p^{\mathrm{V}}_{4c} + p^{\mathrm{V}}_{6c})] \sin(\alpha + 6t)$$
$$+ \frac{1}{4} A_{5q}[(p^{\mathrm{V}}_{4s} - p^{\mathrm{V}}_{6s}) - (p^{\mathrm{V}}_{4c} + p^{\mathrm{V}}_{6c})] \sin(\alpha - 6t) \qquad (25)$$

$$\beta_{5q3} = \frac{1}{4} A_{5q}[(p^{\mathrm{V}}_{2s} - p^{\mathrm{V}}_{8s}) + (p^{\mathrm{V}}_{2c} + p^{\mathrm{V}}_{8c})] \sin(3\alpha + 6t)$$
$$+ \frac{1}{4} A_{5}[(p^{\mathrm{V}}_{2s} - p^{\mathrm{V}}_{8s}) - (p^{\mathrm{V}}_{2c} + p^{\mathrm{V}}_{8c})] \sin(3\alpha - 6t) \qquad (26)$$

$$\beta_{5q5} = \frac{1}{4} A_{5q}[(2\, p^{\mathrm{V}}_{0s} - p^{\mathrm{V}}_{10s})$$
$$+ (2\, p^{\mathrm{V}}_{0c} + p^{\mathrm{V}}_{10c})] \sin(5\alpha + 6t)$$
$$+ \frac{1}{4} A_{5q}[(2\, p^{\mathrm{V}}_{0s} - p^{\mathrm{V}}_{10s})$$
$$- (2\, p^{\mathrm{V}}_{0c} + p_{\cdot 10c})] \sin(5\alpha - 6t) \text{ etc.} \qquad (27)$$

The third subscript is the order of the space harmonic *flux* wave. Thus, β_{5q3} is the 3rd harmonic space flux produced by the 5th space m. m. f. due to i_q.

Consider the meaning of these waves. Each one has an electrical angular velocity of six times normal (referred to its own wave length) with respect to the pole. The wave moves forward if the sign of t is minus, and backward if it is plus[12]. Thus, (**25**) comprises two waves,

12. For instance, in a rotating wave, say (**25**), $\sin(\alpha + 6t)$ must equal a constant. That is, $\alpha + 6t = C$, and $\frac{d\alpha}{dt} = -6$. Thus velocity is backward at 6 times normal speed.

one (the first term) rotating backward at six times synchronous speed with respect to the poles, five times speed with respect to the armature; the other, rotating forward at six times speed with respect to the poles, thus seven times with respect to the armature. These waves are of full pole span; hence the former generates a 5th harmonic, the latter a 7th harmonic voltage in the armature conductors. Eq. (**26**) likewise comprises two 3rd harmonic space waves, one forward, one backward, with respect to the pole at 6/3 or two times speed, thus generating in the conductors a 9th and a 3rd harmonic voltage. Similarly, (**27**) comprises two 5th harmonic space waves which generate a fundamental and 11th. Similarly the waves due to the *direct* component 5th, in eqs. (**21**), (**22**) and (**23**) produce corresponding harmonic voltages. It will be noted that the only fundamental voltages resulting from the 5th space harmonic of m. m. f. are those due to the backward rotating 5th and the forward rotating 7th space flux waves it produces. All other space fluxes which it produces give higher harmonic voltages.

It is shown in Appendix B that for the 5th and higher space harmonics of m. m. f., the permeance series for the cosine distribution is approximately—almost exactly—the same as that for the sine distribution. Thus, making the approximation that

$$p^{\mathrm{V}}{}_{ms} = p^{\mathrm{V}}{}_{mc}$$

then all of the waves due to the 5th m. m. f. which produce fundamental voltage are,

$$\beta_{5d5} = A_{5d}\, p^{\mathrm{V}}{}_0 \cos (5\,\alpha + 6\,t) \qquad \textbf{(29)}$$

$$\beta_{5q5} = A_{5q}\, p^{\mathrm{V}}{}_0 \sin (5\,\alpha + 6\,t) \qquad \textbf{(30)}$$

$$\beta_{5d7} = \frac{1}{2}\, A_{5d}\, p^{\mathrm{V}}{}_2 \cos (7\,\alpha + 6\,t) \qquad \textbf{(31)}$$

$$\beta_{5q7} = \frac{1}{2}\, A_{5q}\, p^{\mathrm{V}}{}_2 \sin (7\,\alpha + 6\,t) \qquad \textbf{(32)}$$

What will be the magnitude and phase of the voltages generated by these waves of flux? In general, voltage is, by definition, *minus* the rate of change of magnetic linkages.[13] Thus

$$e = -\,\frac{d\,\Omega}{d\,t} \qquad \textbf{(33)}$$

The plan is to change the reference of the rotating flux waves from the poles to the armature; then to resolve each wave into two stationary, pulsating components, involving cosine and sine space distributions. The former will produce linkages with phase 1; the latter will not. The linkages thus obtained may then be applied in (**33**).

For illustration, take (**29**). This 5th harmonic wave moves backward at $^6/_5$ speed with respect to the poles, hence at $^1/_5$ speed with respect to the armature thus giving an angular speed, on its own wave length, equal to normal. Let γ be the space angle measured along the armature surface, and reckoned from the axis of phase 1, Fig. 14. Since at $t = 0$ the armature reference (axis of phase 1) and the pole reference (axis of the pole) coincide, the space distribution with reference to the armature will, at that instant, be the space distribution with respect to the pole. Thus the rotating wave expressed with respect to the armature is,

$$\beta_{5d5} = A_{5d}\, p^{\mathrm{V}}{}_0 \cos (5\,\gamma + t) \qquad \textbf{(34)}$$

Resolve this by expansion into

$$\beta'_{5d5} = A_{5d}\, p^{\mathrm{V}}{}_0 \cos 5\,\gamma \cos t \qquad \textbf{(35)}$$

and

$$\beta''_{5d5} = -\,A_{5d}\, p^{\mathrm{V}}{}_0 \sin 5\,\gamma \sin t \qquad \textbf{(36)}$$

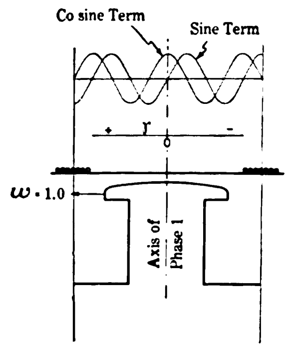

Fig. 14—Space Reference on the Armature, Showing the Position of the Pole and Flux Waves at $t = 0$

These are shown in Fig. 14. The flux expressed in (**35**) produces linkages with phase 1, but (**36**) does not. The linkages are

$$\Omega_{5d5} = C_5\, \phi_{5d5} = \frac{A_{5d}\, C_5\, p^{\mathrm{V}}{}_0}{5} \cos t \qquad \textbf{(38)}$$

where C_5 is the reduction factor[14] due to pitch, distribution and connection of the coils. The instantaneous voltage, expressed as a fraction of normal voltage, is by (**33**) and (**38**)

$$e_{5d5} = \frac{A_{5d}\, C_5\, p^{\mathrm{V}}{}_0}{5} \sin t \qquad \textbf{(39)}$$

But,

$$A_{5d} = \frac{C_5}{5}\, A_{1d}$$

Hence

$$e_{5d5} = \frac{A_{1d}\, C^2{}_5\, p^{\mathrm{V}}{}_0}{25} \sin t \qquad \textbf{(40)}$$

Similarly[15]

13. Linkages of a circuit are understood to be positive when they agree in sign with those produced by a positive current in the circuit.

14. C. A. Adams, bibliography (10).

15. Or these equations may be obtained from the general equations (**58a**) and (**59a**).

$$e_{5q5} = \frac{A_{1q}\, C^2{}_5\, p^V{}_0}{25} \cos t \tag{41}$$

$$e_{5d7} = -\frac{1}{2} A_{1d}\, p^V{}_2 \frac{C_5}{5} \frac{C_7}{7} \sin t \tag{42}$$

$$e_{5q7} = -\frac{1}{2} A_{1q}\, p^V{}_2 \frac{C_5}{5} \frac{C_7}{7} \cos t \tag{43}$$

Consider the phase of these voltages. From eqs. (**1**) and (**2**) i_d is a cosine function of time, and i_q a sine function. But e_{5d5}, produced by i_d, is a *plus* sine

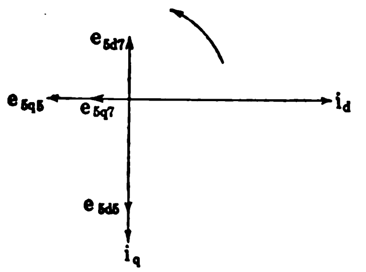

FIG. 15—VECTOR DIAGRAM OF VOLTAGES PRODUCED BY THE 5TH HARMONIC M. M. F.

function. Hence it *lags* a quarter period behind i_d. Similarly, e_{5q5} lags a quarter period behind i_q, which produces it; e_{5d7} leads i_d by a quarter period; and e_{5q7} lags behind i_q by a quarter period. These relations are shown in Fig. 15. It will be noted that e_{qd7} (fundamental) voltage produced by 7th space harmonics of flux (itself produced by the 5th space harmonic of m. m. f.) is a reactive voltage of the same phase relation to the current producing it, as the reactive voltage across a condenser, whereas e_{5d5}, e_{5q5} and e_{5q7} (produced by 5th space harmonics of flux) are of the same nature as the reactive voltage across an inductance. By taking the vector sum of the fundamental voltages due to *all* harmonics[16] (including the fundamental), produced by i_d, and, in addition, the reactive voltages due to the slot and end-winding leakages, the result will be the total reactive voltage produced by i_d, and will thus determine the synchronous reactance x_d for the *direct* component of current. Similarly, x_q is determined for the quadrature component.

The general equations for all harmonics due to the total sine wave (in time) current are given in Appendix A as eqs. (**58a**) and (**59a**).

From these equations the various fundamental voltages[17] have been computed, and are tabulated in Table I, and are shown in Fig. 16 as vectors in relation to the other voltages due to armature current. From these results, the expressions for the reactances are derived in Appendix C.

16. The voltages in Fig. 15 are produced by the 5th space harmonic of m. m. f. alone. There is a similar set of voltages for the 7th, 11th, 13th, 17th, 19th, etc., harmonics of m. m. f.

17. While only the fundamental voltages are derived in detail, equations (**58a**) and (**59a**) contain the harmonics.

It will be helpful to sum up the points thus far established. The general plan, it will be remembered, is to determine, first, all of the component voltages produced by armature currents, such voltages comprising (a) all of those generated by flux emanating from the armature surface, *i. e.*, the air-gap flux, (b) that due to flux crossing the slots, (*i. e.*, slot leakage) and (c) that due to end winding leakage; and, second, all voltages due to current in the field winding; then, by superposition of all significant components, to determine the resultant, which is the terminal voltage. In the foregoing, the voltages due to the air-gap fluxes which are produced by armature current have been determined.

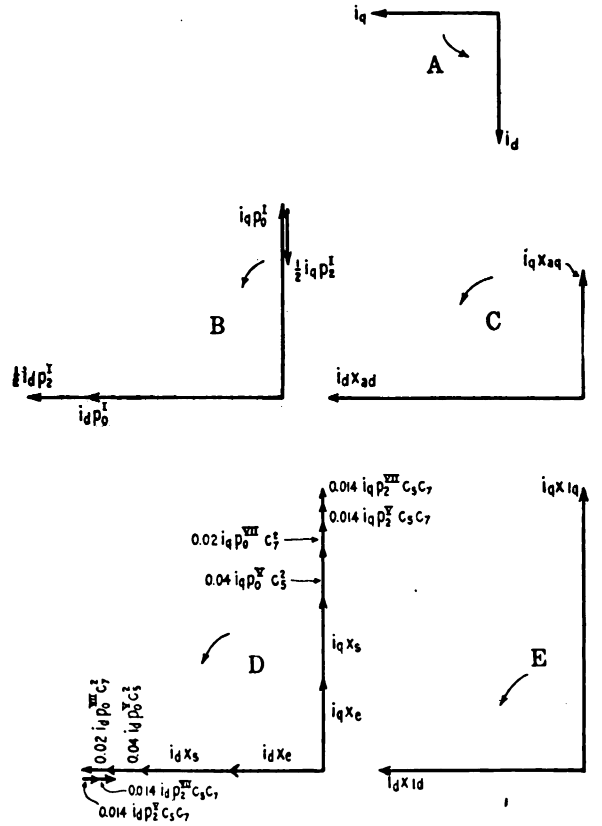

FIG. 16—FUNDAMENTAL VOLTAGES DUE TO ARMATURE CURRENTS

A—Components of armature current
B—Component armature reaction voltages
C—Resultant armature reaction voltages
D—Component leakage reactance voltages
E—Resultant leakage reactance voltages (D and E magnified in scale, compared with B and C)

The voltages due to slot and end winding leakage have been previously determined.[18] Hence all voltages due to armature current are accounted for. In Appendix C the important ones of these are assembled in expressions for reactance.

Field Current Phenomena. The other source of flux is the field current. This current is due to the exciter voltage, assumed to be constant, and to such harmonic

18. Bibliography 8.

voltages as are short-circuited by the field winding. The rotating space harmonic m. m. fs. produced by the armature current are of odd order, and rotate at odd fractions or multiples of synchronous speed with respect to the armature. Hence their electrical angular speed (on the harmonic base) with respect to the field pole and field winding must be of even order; because one times speed is always added to or subtracted from the odd term. For instance, the 5th rotates backward at 1/5th speed with respect to the armature, thus 6/5th with respect to the pole. Hence it generates a 6th harmonic. The 7th rotates forward at 1/7th speed with respect to the armature, hence 6/7th with respect to the poles. Hence it also generates a 6th harmonic in the field winding.

Therefore, the general form of the field current will be a Fourier Series of even harmonic terms, thus

$$I = I_0 \cos 2t + I_4 \cos 4t + \ldots . + I'_2 \sin 2t + I'_4 t + \ldots . \quad (44)$$

But inasmuch as, in a three-phase machine, the 5th is the lowest order[19] of rotating harmonic m. m. f. (excepting the fundamental), the 6th harmonic must be the lowest order harmonic in the field current. Moreover, since the 7th m. m. f. harmonic also produces only a 6th in the field current, and since the next existing space harmonics are the 11th and 13th, both of which generate a 12th harmonic in the field winding, and next the 17th and 19th, which generate an 18th, it follows that the only harmonics in the field winding are multiples of the 6th.

But these are all of practically negligible magnitudes. While the 6th harmonic ripple may, in rare cases, be detected in the field current under the condition of balanced three-phase currents, and although it does very slightly affect the fundamental voltage, its influence is practically insignificant. Hence only the effects of the average term I_0, which is sustained by the constant exciter voltage, are considered.

The voltage due to the flux produced by I_0 has been adequately treated before.[20] The flux wave thus produced is of the general shape indicated in Fig. 17, and hence contains a fundamental and odd harmonics. The component harmonic waves are, of course, stationary with respect to the poles and therefore generate replica voltage waves in the individual armature conductors. The flux wave is determined, as in Figs. 5, 6, 7 and 8, by graphic field plot from a scale drawing of the armature and field pole.

If there should be a field m. m. f. in the *quadrature* axis, there would be another flux wave produced, symmetrical about that axis, hence containing only odd terms—fundamental and odd harmonics.

Significance of Various Voltages. Consider now some aspects of the various fluxes and voltages. Which of them are important? Which of the fluxes determine the leakage reactance; which, the armature reaction?

Take the harmonic voltages first. These are due, as already explained, to (a) a set of rotating flux waves produced by a sine wave (in time) current; (b) an additional set of rotating waves for each time harmonic in the armature current. In the various sets, the speed of rotation of the respective *space* harmonics (*i. e.*, of the same pole span) is proportional to the order of the time harmonic producing it, and the amplitude is proportional to the amplitude of the time harmonic current; (c) the space harmonics of the field flux; and (d) the effects of permeance waves due to slots.[21]

How important are these harmonic voltages? Some are of no importance because they are of negligible magnitude. This may be due either to small amplitude of the flux harmonic, or to reduction by the connection and space phase of armature conductors. It is well known, for instance, that either a Y connection or $2/3$ coil pitch eliminates the third harmonic; $4/5$ pitch, the 5th; $6/7$ pitch, the 7th, etc.; and the distribution of coils greatly reduces any which may remain.[22] So in many cases the harmonics may be neglected because they are not appreciable.

Therefore, since the harmonics do not significantly influence the regulation and power relations, principally to be considered here, they will be neglected. If their evaluation, for other purposes, is ever required, the foregoing treatment, particularly eqs. (**58a**) and (**59a**), constitutes a basis for their determination.

Consider the fundamental voltages. They are due to

(a) fundamental space component of flux due to the *direct* component of armature m. m. f., *i. e.*, *direct* armature reaction.

(b) fundamental space component of flux due to the *quadrature* component of armature reaction.

(c) 5th space harmonic flux,[23] rotating backward at $1/5$ speed, and due to the *direct* component of armature current.

(d) 5th space harmonic,[23] rotating backward, and due to the *quadrature* component of current.

(e) two corresponding components, (*i. e.*, *direct* and *quadrature*) of the 7th space harmonics, rotating forward at $1/7$ speed.

19. There is an exception to this in the case of a delta-connected machine in which the circulating currents (third harmonic and its multiples) produce space third harmonics of m. m. f. and odd multiples thereof. However, these m. m. fs. rotate at such a speed as to induce in the field winding 6th, 12th, 18th, etc., time harmonics of current.

20. Bibliography 7, and Appendix of 8.

21. This is neglected in the present treatment. It is a different factor from the ripples due to current concentration, the latter being taken into account. The former have been treated by Lyon. See bibliography 7.

22. In most modern alternators the harmonics are practically all thus screened out, leaving the terminal generated voltage almost a true sine wave. Bibliography 10.

23. Each of these, *i. e.*, (c), (d) and (e), comprises two flux components: one due to the 5th space harmonic of m. m. f.; the other, to the 7th. See Table I.

(f) two components of the 11th rotating backward at $^1/_{11}$ speed;[24] and so on.

(g) slot leakage flux produced by both components (*direct and quadrature*).

(h) end-winding leakage flux produced by both components.

(i) fundamental space components of flux due to field m. m. f. in the *direct* axis.

(j) fundamental space component of flux due to field m. m. f. in the *quadrature* axis.

Consider these in detail. The terms (a) and (b)

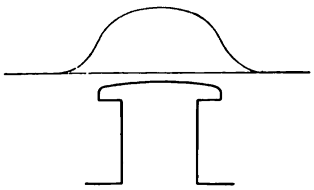

FIG. 17

are the usual vectors of voltage produced by the flux of armature reaction; these are $i_q\, x_{aq}$ and $i_d\, x_{ad}$ in diagram, Fig. 18. (i) corresponds to the *nominal* voltage e_d. (j) is an added similar term e_q, Fig. 19,

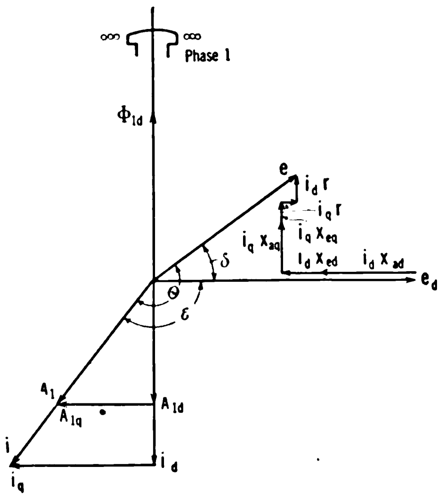

FIG. 18—VECTOR DIAGRAM FROM EQUATIONS. NEGLECTS SATURATION

for the quadrature axis. (g) is the usual slot leakage $i_q\, x_s$, and $i_d\, x_s$, Fig. 16D, which is independent of currents in any other slot, and is therefore the same for single or polyphase currents for full pitch coils. They are, however, different for fractional pitch. It may therefore be treated as external reactance,[25] provided the slot contains current of one phase only. Slot reactance is obviously the same for the *direct* and *quadrature* components of current. (h) corresponds to the usual end winding leakage reactance $i_q\, x_e$ and $i_d\, x_e$, Fig. 16D. There is some mutual reactance between phases, and hence it is not the same for single-phase and polyphase currents, and hence can not be considered as external reactance. It is here assumed to be the same for the *direct* as for the *quadrature* component of current.

In Appendix C, expressions for the various reactances are derived.

VECTOR DIAGRAMS

From the foregoing, and the results in Appendix C, the vector diagram, neglecting saturation, can be constructed. The diagram, of course, will contain the same quantities as the well-known Blondel diagram, with the rather trifling exception discussed above, regarding the leakage reactance voltages.[26]

From Table I, the voltages due to armature reaction, *i. e.*, to the space fundamentals of flux, are

$$-j\, A_{1d}\left(p_0{}^{\mathrm{I}} + \frac{1}{2}\, p_2{}^{\mathrm{I}}\right) = -j\, \dot{i}_d\, x_{ad}$$

and

$$-j\, A_{1q}\left(p_0{}^{\mathrm{I}} - \frac{1}{2}\, p_2{}^{\mathrm{I}}\right) = -j\, \dot{i}_q\, x_{aq}$$

The voltages due to leakage reactance, derived in Appendix C, are

$$-j\, \dot{i}_d\, x_{ld}$$

and

$$-j\, \dot{i}_q\, x_{lq}$$

Taking the fundamental flux ϕ_{1d}, *direct* axis, as the time reference vector, the vector diagram in Fig. 18 is constructed. By the convention adopted in the equations, $\dot{i}_q$ was taken as lagging with respect to $\dot{i}_d$. This corresponds to a *motor* load; hence in Fig. 18, according to the definition, the power-factor angle θ is greater than 90 deg., *i.e.*, $>$ .25. Redrawing Fig. 18 in Fig. 20, the conventional relations are shown, in which i_q is reversed, thus a generator load. Also the reactances are combined, since saturation is in this particular case neglected.

$$x_d = x_{ad} + x_{ld}$$
$$x_q = x_{aq} + x_{lq}$$

The vectors in Fig. 20 are the *induced*, not the consumed, voltages.

Introducing an excitation current in a field winding around the quadrature axis, brings in an additional voltage e_q as shown in Fig. 19. The general power-angle relations are derived in Part II from this diagram. An approximate method, due to Blondel, for taking

24. When irregular armature windings are used, for instance, fractional slots per pole and then additional harmonics occur. These are important since they may create serious vibration in the stator frame; and, in the case of induction motors, may significantly increase the leakage reactance. Their computation is beyond the scope of this paper.

25. The effect of currents of different phases in the same slot, as in fractional coil pitch, is accounted for by appropriate factors in the calculation of slot leakage.

26. In the present treatment these comprise all fundamental voltages except those produced by the two space fundamental flux waves.

saturation into account will be referred to in Part II and also in Appendix D, in which Fig. 20 will be interpreted in terms of the familiar Potier diagram for cylindrical rotor machines.

An idea of relative phase and magnitude of voltages may be obtained from an inspection of Table I. Referring to Fig. 16D, in which the phase relation of the various vector voltages of Table I is shown,[27] it will be noted that the only ones which do not have the same phase relation with respect to the current which causes them, are those which involve products $C_5\,C_7$, $C_{11}\,C_{13}$, etc.—that is, those terms in which a flux of one space order is produced by m. m. f. of another space order.

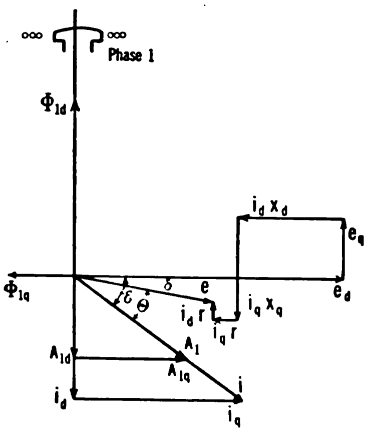

FIG. 19

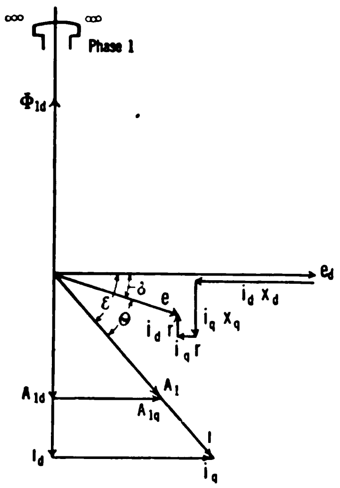

FIG. 20—VECTOR DIAGRAM—USUAL CONVENTIONS

The diagrams show nothing above the 7th, since the next term involves the 11th and 13th, and is entirely negligible. They are, in other words, only those terms which involve second harmonic permeance coefficients for m. m. f. space orders > 1.0, such as p_2^{V}, p_2^{VII}, etc. They are given in eq. (7c) Appendix C. It will be observed in Fig. 16D that the only such terms are

$$0.014\, i_d\, p_2^{V}\, C_5\, C_7$$
$$0.014\, i_d\, p_2^{VII}\, C_5\, C_7$$

27. In the diagram, currents are substituted for corresponding armature reactions.

TABLE I

FUNDAMENTAL VOLTAGES

A. Due to Direct Component of Armature Current.

n	m	k_n	Order of Flux Wave	Amplitude and Phase of Fundamental Voltages
1	0	1	1	$-j\,A_{1d}\;p_0^{I}$
1	2	1	1	$-j\,\dfrac{A_{1d}\,p_2^{I}}{2}$
5	0	−1	5	$-j\,\dfrac{A_{1d}\,C_5^2\,p_0^{V}}{25}$
5	2	−1	7	$+j\,\dfrac{A_{1d}\,C_5\,C_7\,p_2^{V}}{70}$
7	0	1	7	$-j\,\dfrac{A_{1d}\,C_7^2\,p_0^{VII}}{49}$
7	2	1	5	$+j\,\dfrac{A_{1d}\,C_7\,C_5\,p_2^{VII}}{70}$
11	0	−1	11	$-j\,\dfrac{A_{1d}\,C_{11}^2\,p_0^{XI}}{121}$
11	2	−1	13	$+j\,\dfrac{A_{1d}\,C_{11}\,C_{13}\,p_2^{XI}}{286}$
13	0	1	13	$-j\,\dfrac{A_{1d}\,C_{13}^2\,p_0^{XIII}}{169}$
13	2	1	11	$+j\,\dfrac{A_{1d}\,C_{13}\,C_{11}\,p_2^{XIII}}{286}$

B. Due to Quadrature Component of Armature Current

n	m	k_n	Order of Flux Wave	Amplitude and Phase of Fundamental Voltages
1	0	1	1	$-j\,A_{1q}\,p_0^{I}$
1	2	1	1	$+j\,\dfrac{A_{1q}\,p_2^{I}}{2}$
5	0	−1	5	$-j\,\dfrac{A_{1q}\,C_5^2\,p_0^{V}}{25}$
5	2	−1	7	$-j\,\dfrac{A_{1q}\,C_5\,C_7\,p_2^{V}}{70}$
7	0	1	7	$-j\,\dfrac{A_{1q}\,C_7^2\,p_0^{VII}}{49}$
7	2	1	5	$-j\,\dfrac{A_{1q}\,C_5\,C_7\,p_2^{VII}}{70}$
11	0	−1	11	$-j\,\dfrac{A_{1q}\,C_{11}^2\,p_0^{XI}}{121}$
11	2	−1	13	$-j\,\dfrac{A_{1q}\,C_{11}\,C_{13}\,p_2^{XI}}{286}$
13	0	1	13	$-j\,\dfrac{A_{1q}\,C_{13}^2\,p_0^{XIII}}{169}$
13	2	1	11	$-j\,\dfrac{A_{1q}\,C_{13}\,C_{11}\,p_2^{XIII}}{286}$

In the above terms, $A_{1d} = i_d$ and $A_{1q} = i_q$. See "notation."

These are *reversed* with respect to the other voltages produced by i_d. The corresponding terms produced by i_q are,

$$0.014\, i_q\, p^{V}{}_2\, C_5\, C_7$$
$$0.014\, i_q\, p_2{}^{II}\, C_5\, C_7$$

which *add on* to corresponding voltages produced by i_q.

What about the magnitude? The product $C_5 C_7$ may be of any value between zero and a maximum value = 1.0 for a three-phase machine. It is zero if the coil pitch is either $^4/_5$ or $^6/_7$, and greatly reduced for other pitches.[28] It is greatly reduced also by coil distribution.[29] The permeance coefficients $p_2{}^V$ and

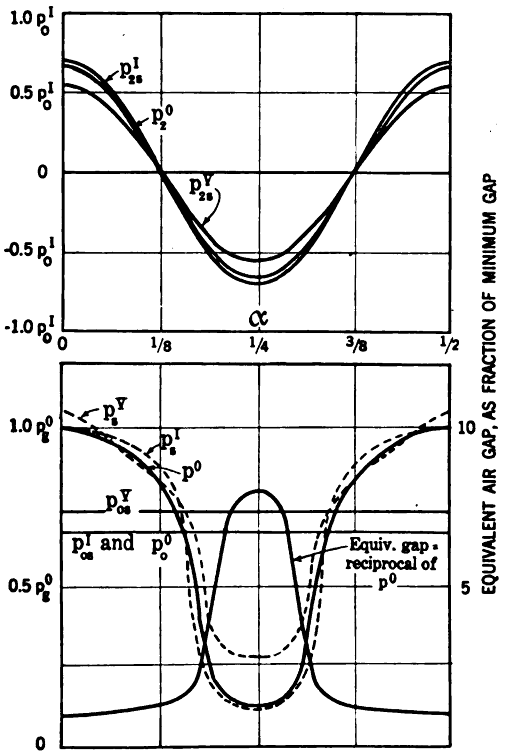

FIG. 21—PERMEANCE DISTRIBUTION DETERMINED FROM FIELD PLOTS. ALSO EQUIVALENT AIR-GAP

$p_2{}^{VII}$ are of the order of 50 per cent of $p_0{}^I$. Thus the maximum possible value of each term is of the order of ½ of one per cent of the armature reaction voltage due to i_q or to i_d. This would give a maximum variation in leakage reactance voltage with pole position, of the order of ± 1 per cent of the armature reaction voltage; and in many cases, on account of fractional pitch, etc., it would be practically zero. Therefore the conclusion is that in many salient pole machines the variation in leakage reactance with pole position is entirely negligible, and is of small magnitude in any case approaching the usual design practise.

PRACTICAL APPLICATION OF RESULTS

The application of the method given here requires numerical data for the zero and second space harmonic of permeance for each significant harmonic m. m. f. The harmonic m. m. fs. are easily computed, and are all expressed in Table I in terms of the fundamental m. m. f. component. But the permeance coefficients must be determined from field plots[30] such as shown in Figs. 5, 6, 7, 8 and 9. From such plots, the permeance curves are determined and analyzed to obtain the required value of the average and the second harmonic coefficients. Partial analysis of these particular plots is shown in Fig. 21.

In order to avoid having to plot, as above, the flux distribution for each significant harmonic, including the fundamental, an approximation is made as follows: A plot is made for the zero harmonic, as in Fig. 5, which results are shown also on Fig. 21. In addition the latter shows a curve of "equivalent air-gap," taken as the reciprocal of the permeance for the zero harmonic. From this and the curve in Fig. 10, derived in Appendix B, the permeance curves for any harmonic can be obtained, as in Fig. 11. These are then analyzed for the zero and second harmonic. The results thus obtained for the particular case here illustrated are compared in Table II with those obtained directly from the plots and are also compared in complete curves in Fig. 12. It will be noted that the agreement is very satisfactory. The only discrepancy worth noting is between $p_{2c}{}^I$ and $p_{2s}{}^I$, which are, from plots, respectively 0.43 and 0.47. The value derived from Figs. 10 and 21 is 0.44.

TABLE II

COMPARISON OF PERMEANCES OBTAINED DIRECTLY FROM FIELD PLOTS, AND DERIVED FROM FIGS. 10 AND 21.

	Values from plots	Values Derived from Figs. 10 and 21
$p_{0c}{}^I$	$0.67\ p^0{}_g$	$0.66\ p^0{}_g$
$p_{0s}{}^I$	$0.67\ p^0{}_g$	
$p_{2c}{}^I$	$0.43\ p^0{}_g$	$0.44\ p^0{}_g$
$p_{2s}{}^I$	$0.47\ p^0{}_g$	
$p_{0c}{}^V$	$0.74\ p^0{}_g$	$0.73\ p^0{}_g$
$p_{0s}{}^V$	$0.73\ p^0{}_g$	
$p_{2c}{}^V$	$0.38\ p^0{}_g$	$0.37\ p^0{}_g$
$p_{2s}{}^V$	$0.37\ p^0{}_g$	

$$\frac{\text{min. gap}}{\text{pole pitch}} = 0.02 \qquad \frac{\text{pole arc}}{\text{pole pitch}} = \frac{2}{3}$$

$$\frac{\text{max.}}{\text{min.}}\ \text{gap} = 1.5 \qquad p_g{}^0 = 1.5\ p_0{}^I$$

28. Of course it would be zero also for a pitch of either $^2/_5$ or $^4/_7$, etc.

29. C. A. Adams, Bibliography 10.

30. Comprehensive treatments of flux plotting are being prepared by engineers of the General Electric Company, for presentation at an early date.

The above simplifying assumptions are fully discussed in Appendix B.

The general plan, therefore, is to obtain a permeance curve for the zero harmonic for the machine under consideration, and from that, the "equivalent air gap" curve. Then with the aid of Fig. 10, plot a group of curves as in Fig. 11. An analysis of these will give the required $p_0{}^n$ and $p_2{}^n$.

Research Relations Between Engineering Colleges and Industry

BY W. E. WICKENDEN[1]

Member, A. I. E. E.

IN our present easy-going attitude toward language, we are tempted to use the word "research" to mean so many things that we have no word left to mean research. The effort to sell a research program to industry has induced us to translate the word into such unmistakably practical terms as "in a word it is invention," to quote a recent official pamphlet.

In the present discussion it is probably safe to assume that we are dealing only incidentally with disinterested pioneer work in the realm of pure knowledge, which is the scientist's calling. Engineering is always utilitarian and concrete, and most engineers abandoned the alternative of becoming physicists, chemists or mathematicians in order to become engineers. This observation holds for professors as well as practitioners. Every professor of engineering worthy of the title, however, is qualified to investigate engineering problems involving elements of novelty which call for extended observation, refined technique, and a resort to fundamental principles. The indications are that both the men and facilities available for these purposes in the engineering colleges are now being utilized very inadequately, to the detriment of both industry and education.

A fairly complete survey of the engineering colleges in the United States shows that not less than 58 have organized arrangements for research, at least on paper. Included in this number are 41 institutions which have organized plans through which the services of the engineering staff are made available in consulting capacities to industries, public service utilities and others. If we include those institutions in which research is fostered on a purely individual basis, the total rises to 110.

The total expenditures of the organized research departments are not less than $1,250,000 per annum and may reach as high as $1,500,000. Of such expenditures in the academic year 1924-'25, approximately 11 per cent represented direct appropriations for research by the several states, 40 per cent funds allotted by the colleges from their general funds, and 49 per cent funds derived from outside sources, principally from public, professional and industrial organizations.

At least 34 institutions have full-time research staffs, with between 250 and 300 men so engaged. To this number may be added about 350 more who render part-time research service for definite compensation and about 200 who give part-time service in organized departments without special compensation. The number engaged on a purely individual basis is difficult to estimate.

Impressive as these totals are, it must be remembered that there are two corporations in the electrical industry which spend on research more than double the total outlay of the engineering colleges and that at least two in other fields exceed the total of the colleges. Organizations at this end of the industrial scale are unlikely to turn to the engineering colleges to get their problems solved. Big business can probably be induced to give support to organized investigation in engineering colleges only on the plea that such activity is necessary in order to maintain the proper setting and staff for the training of the grade of engineers big business requires. Pure research rather than engineering investigation seems likely to get the bulk of the financial assistance from this source, and it seems probable that it will be disbursed through some intermediary or clearing house, instead of passing directly to individual colleges or professors. The present campaign of the National Academy of Sciences for a national research endowment, under the leadership of Mr. Herbert Hoover, is working successfully on this principle.

At the other end of the scale are innumerable, small units of industry which live from balance sheet to balance sheet, with no consciousness of research needs and little margin for the support of research activities. Such organizations occasionally meet acute problems outside the scope of their normal routine and staff. When these emergencies call for investigation, a college professor or laboratory staff may fit the need admirably, but is this not first aid rather than research?

Many of these smaller units of industry are concerned with the traditional arts rather than with the applications of modern science. They are likely to remain deaf to any appeal to support research for the sake of repay-

*Director of Investigation, Society for the Promotion of Engineering Education, 33 West 39th St., New York City.

Presented at the A. I. E. E. Regional Meeting of Dist. No. 5, Madison, Wis., May 6-7, 1926.

ing their debt to science or for the sake of maintaining a wide margin between pure knowledge and practical invention. It is just these industries, however, which are most apt to be handicapped by the decline of sporadic invention and likely to profit most relatively, from an adequate program of research. Support for such investigation is not to be expected from the single units of such industries, but their state and national trade associations are the natural agencies to foster such activities. There are attractive possibilities of dividends in the form of better methods, economies and more exact control in the present state of the art. Research, looking in advance of the present art, is a form of mutual insurance covering the risks of supersession or revolutionary changes in the art.

A recent report of the Babson Statistical Organization announced that an English factory was testing out the production of a flexible, colorless, resilient, non-inflammable glass of organic origin. It went on to say:

> "The point of this letter, however, is not only about glass. This is but one of numerous far-reaching discoveries which have recently been reported. We believe that business is entering an era of the most rapid and revolutionary changes in the chemistry and physics of manufacturing. To those who are quickest in taking advantage of such discoveries, they present unlimited opportunities, but the manufacturer, merchant or investor who is asleep to these changes will be hurt.
>
> "The time has passed when advertising alone will get sales. The two best salesmen today are 'a better product' and 'a cheaper way of making it.' Research opens the way to both. Furthermore, since the most deadly competition is not between concerns, but between industries, we urge clients to combine their energies with others in the same line of business. This saves duplication of efforts, leads to maximum results and keeps one best informed about all impending developments. Make use of the help which the United States Bureau of Standards at Washington stands ready to give you, and also that of other technical organizations of high standing. Cease worrying about gaining the temporary advantage of exclusive patents, and combine your resources in the way that will do most to permanently help your industry."

It is significant that the occasion which brought the above report to the writer's desk was a request from its authors for a complete list of the engineering colleges with facilities for organized research in cooperation with industry. The writer is strongly of the opinion that trade and industrial associations offer by far the most promising agencies through which to promote industrial cooperation with the colleges in engineering research. The support of such activities by individual corporations is apt to be sporadic while trade associations can effectively maintain a continuing relation. The results of work supported by individual corporations are apt not to be widely disseminated or used. A good deal of such support is frankly on a courtesy basis, without a vital interest in its effectiveness or utilization, and with little genuine collaboration between the college and the industry.

A trade association, administering its funds in trust for its constituency and genuinely concerned to show a good return for the investment, provides an excellent medium for the joint shaping of research projects and a widely ramified channel through which to disseminate results. It would seem that the most fruitful result may be expected when a trade association concentrates its cooperative program at a single college, or at a small group of institutions at most. Such work ought not to be located on a courtesy basis or split up on a political basis, but should seek to capitalize distinctive advantages of men, plant and environment. There is a definite loss when such resources are spread over many institutions as a fairly ineffectual mist, when they might be concentrated into a fairly powerful stream. In this respect the European situation is far better ordered than our own. The policy of concentrating resources abroad has led to the upbuilding of a group of notable and distinctive research centers which are the principal factor in attracting and holding to educational and research work the outstanding authorities in the several fields. The result has been to give the several institutions an individuality quite unknown among us.

The writer does not feel that the colleges can rest their case for industrial backing for their research programs on the needs of the colleges or on an assumed sense of obligation on the part of industry to see that the colleges obtain the men, money and facilities needed to do their best work. The industries recognize these obligations rather vaguely, and when confronted by the competing pleas of 100 to 150 institutions are justified in feeling rather helpless. The Babson report, however, speaks in the tongue which industry understands and to which it responds.

The work being done at Cincinnati in cooperation with the Tanners' and the Lithographers' national organizations, the power brake studies at Purdue in cooperation with the American Railway Association, the studies in warm air heating and ventilating at Illinois, and the great project of the Portland Cement Association in association with Lewis Institute are worthy examples of adequately supported, nationally backed and effectively concentrated research programs, involving real collaboration between colleges and industries and leading to results of great significance and value.

A 7,500,000-c. p., 900-watt searchlight is being installed on the Broadmoor Hotel's Summit House on Cheyenne Mountain, overlooking Colorado Springs and Manitou, Colorado. The highest beacon in the world is said to be the 5,000,000-c. p. aviation light on Sherman Hill, Wyoming, 8600 ft. above sea level.

A Flux Voltmeter for Magnetic-Tests

BY G. CAMILLI[1]

Associate, A. I. E. E.

Synopsis.—*A voltmeter is described for a-c. circuits the voltage indications of which are directly proportional to the maximum flux density, regardless of the wave shape of the voltage. While the instrument is suitable for many varieties of magnetic tests, its most important application is to the reduction of transformer core-loss measurements to sine-wave basis. Test data indicate excellent accuracy for the meter in this application in comparison with other schemes or outfits used at the present time for that purpose. Losses determined by this new meter are, in general, appreciably larger than those determined by the older methods.*

The new meter makes it unnecessary to use, for reliable results, large generators to reduce the wave distortion caused by transformer excitation loads, and permits the use of any generator that will carry the load thermally.

Introduction

This paper describes a voltmeter for a-c. measurements designed so that its indications are directly proportional to the maximum value of a-c. magnetic flux regardless of wave shape. It is graduated in terms of equivalent effective sine-wave voltage, so that at any wave shape the maximum magnetic flux is the same as the maximum value of sine-wave flux generating a sine-wave voltage of the same effective value as the indication of this voltmeter. The instrument is particularly useful in core-loss measurement and for exploring alternating-flux magnetic networks. It is useful also for the determination of the form factor of a-c. voltages, and, with slight modifications, the form factor of alternating currents.

It is recognized that certain circuit characteristics are functions of the maximum value of the alternating wave. For instance, hysteresis loss and also magnetizing current to a large extent are functions of the maximum flux density, not functions of r. m. s. values of current, voltage or flux. The problem of measuring this maximum flux has not been satisfactorily solved by other methods though ballistic galvanometers and core-loss voltmeters or correction outfits have been developed and used for the purpose. The ballistic galvanometer is not well suited to a-c. measurements, and core-loss voltmeters have serious limitations as will be pointed out later.

The instrument developed by the writer for this purpose, called a flux voltmeter, consists essentially of a rectifier in series with a d-c. voltmeter. Across these two in series is impressed the voltage which is generated in a coil surrounding the core under test in which the alternating flux exists. Under this condition, the voltmeter indications, as will be proved later, are proportional to the maximum magnetic flux in the core.

Theory of the Instrument

The principles underlying the functioning of the flux voltmeter are two:

First, in an a-c. circuit, the maximum alternating flux density is proportional to the arithmetic average value of the reactive voltage drop regardless of the wave shape of the voltage, provided the wave does not cross the zero line more than twice per cycle.

Second, if an alternating voltage is rectified without changing the wave shape, and is impressed on a d-c. voltmeter, the meter indication is proportional to the arithmetic average value of the rectified wave which is the same as the arithmetic average value of the unrectified a-c. wave.

The proof of the first theorem is as follows:

Let e be the instantaneous voltage consumed in the inductance of a circuit, and ϕ the flux associated with that circuit. By elementary theory,

$$e = K \frac{d\,\phi}{d\,t} \tag{1}$$

where K is constant of the circuit. It follows from (1) that

$$e\,d\,t = K\,d\,\phi$$
$$\int e\,d\,t = K \int d\,\phi$$

The integral of $d\,\phi$ is obviously the change in the flux; and its maximum value, that is, the maximum change in flux, is obtained by finding the maximum change in the integral of $e\,d\,t$. Referring to Fig. 6, the integral of $e\,d\,t$ is the area of the voltage wave (alternately positive and negative, plus a constant of integration), and the maximum change in $\int e\,d\,t$ is the area of half a cycle of the voltage wave. Thus,

$$\int_{t_1}^{t_2} e\,d\,t = K \int_{\phi\ \text{lower limit}}^{\phi\ \text{upper limit}} d\,\phi$$

$= K$ times the maximum change in flux.

The area of one-half cycle of the voltage wave may be also determined, however, if we know the average voltage, by the equation,

$$\int_{t_1}^{t_2} e\,d\,t = \text{area of half-cycle}$$
$$= e_{avg}\,(t_2 - t_1)$$

The maximum change in flux is therefore proportional to e_{avg} since $(t_2 - t_1)$ is a constant, being the duration of half a cycle dependent only on the frequency of the circuit. Since, also, the flux density is proportional to the total flux, the maximum a-c. flux

1. Transformer Engineering Department, Pittsfield Works, General Electric Company.

Presented at the Regional Meeting of District No. 1 of the A. I. E. E., Niagara Falls, N. Y., May 26-28, 1926.

density, B_{max}, must be proportional to the maximum total a-c. flux, ϕ_{max}, and thus we have,

$$B_{max} \text{ is proportional to } e_{avg}.$$

The factor of proportionality is taken care of as follows: the meter scale being graduated in terms of effective sine-wave voltage, it follows that the alternating flux density in the circuit under test corresponds to an effective sine-wave voltage of the same equivalent value as the indication of the flux voltmeter. In other words, for any given wave shape of voltage, the flux voltmeter indicates its equivalent sine-wave value, which would cause the same maximum flux or

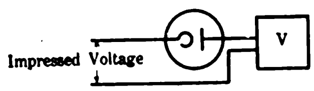

FIG. 1

flux density. On pure sine-wave voltage, the indications of the flux voltmeter are naturally identically the same as those of an ordinary r. m. s., a-c. voltmeter. In fact, the meter is calibrated in this way.

The reason for the limit to wave distortion mentioned above, namely, that the wave must not cross the zero

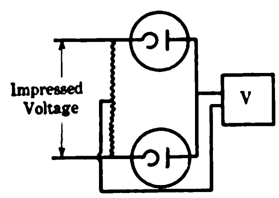

FIG. 2

more than twice per cycle, may be understood as follows.

Considering the positive half cycle of the voltage wave, assume that this dips through the zero and has a negative portion. The positive portions of the half-cycle will add to the flux in accordance with the integral of $e\,d\,t$, and the negative portion will subtract by the

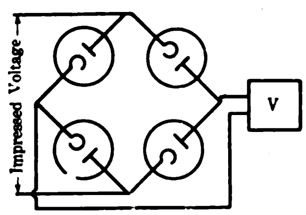

FIG. 3

same integral. Since the flux voltmeter rectifies the entire wave, this small negative portion will also be rectified and instead of reducing the voltmeter reading will increase it. The reading of the voltmeter, therefore, even though it still represents the arithmetic average of the voltage wave, will not truly represent the maximum of the flux wave. This limitation, however, is hardly a handicap because it is almost inconceivable that a commercial voltage wave could be so distorted as to cross the zero more than twice per cycle.

Description of the Instrument. The practical construction of an instrument to meet these requirements is quite simple. Vacuum tubes are used for rectification, and a high-resistance, d-c. voltmeter to read the arithmetic average value of the rectified wave.

A diagrammatic sketch of the simplest possible con-

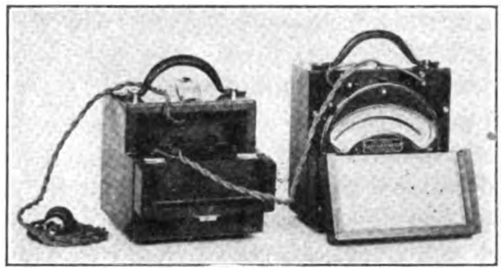

FIG. 4

struction is shown in Fig. 1 which shows a single rectifier tube in series with a d-c. voltmeter. The voltage to be measured is impressed across the voltmeter and rectifier in series; and the meter indication is then proportional to the integral of the impressed voltage.

Although the scheme of Fig. 1 is extremely simple, it suffers from two disadvantages: first, due to half-wave rectification the frequency of the pulsations of the rectified wave is one-half of that of the completely rectified wave, and it was observed that with 25-cycle impressed voltage, the needles of some voltmeters would vibrate like a frequency-meter reed. The second disadvantage is that with half-wave rectification the deflection of the meter is reduced to one-half. To increase the deflection would require a reduction in the resistance of the meter to one-half, double the current, all double the losses,—all of which would be undesirable.

The scheme shown in Fig. 2 using two tubes and an auto-transformer for rectifier yields full-wave rectification and better characteristics in general, except that the exciting current drawn by the shunt auto-

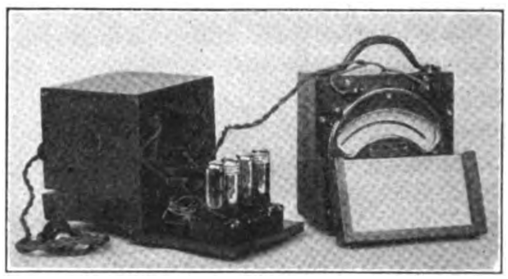

FIG. 5

transformer might be objectionable, especially when instrument transformers are used.

The connection found most satisfactory is shown diagrammatically in Fig. 3, consisting of a four-tube, full-wave rectifier in combination with a d-c. voltmeter.

The instrument used for the investigations described below was constructed in accordance with the scheme of Fig. 3. Fig. 4 is a reproduction of a photograph of the outfit, showing the rectifier and voltmeter in separate cases, although some units now under construction incorporate the rectifier and voltmeter in one case. Fig. 5 shows the contents of the rectifier unit,—four vacuum tubes and one filament-current transformer. The purpose of the filament-current transformer is to obtain the necessary filament current from the lighting circuit instead of from the circuit under test. To draw this current from the circuit under test would be doubly objectionable: it would load the potential transformers in the circuit unnecessarily and reduce their accuracy, and it would change the calibration of the instrument with varying load voltage. Supplying the filament excitation from a lighting circuit eliminates both these difficulties, especially the latter, inasmuch as variations of the voltage of the lighting circuit, within the range of 110 to 125 volts, have no sensible effect on the calibration of the instrument.

The voltmeter is graduated in terms of equivalent effective r. m. s. sine-wave voltage, so that the maximum flux density in the core under test is the same as the maximum flux density for an r. m. s. sine-wave voltage of the same value as that indicated by the flux-voltmeter.

The constants of the tubes, meter and transformer are as follows:

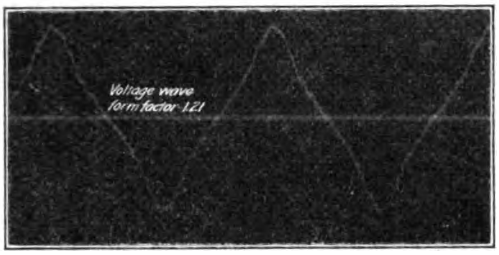

Fig. 6

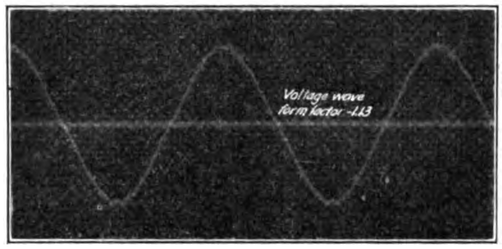

Fig. 7

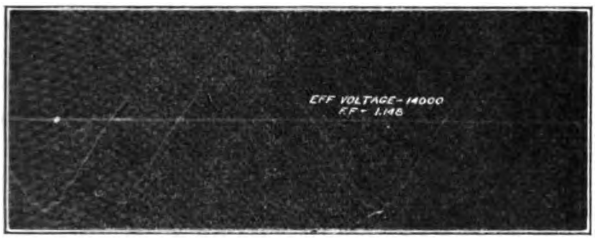

Fig. 8

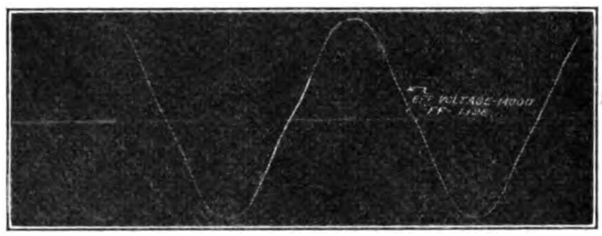

Fig. 9

Fig. 10

Fig. 11

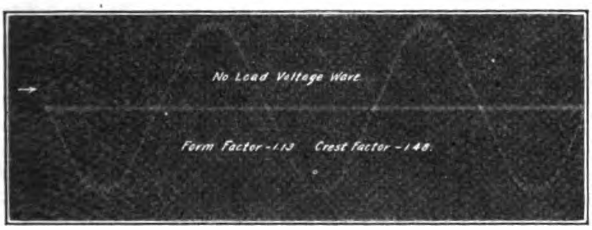

Fig. 12

Tubes: Radio Corporation of America type, *U X*-120 tubes, well known to the radio public. Although this tube is of the three-element type, its grid and plate are connected together so as to act as a single electrode for rectification. The resistance of the tube in this connection is of the order of 5000 ohms. Rated filament voltage three volts, filament current 0.125 amperes.

Transformer: primary rated 110—125 volts, 25—60 cycles; four secondary windings, one for each tube, each rated 3—3.75 volts.

Voltmeter: d'Arsonval type, d-c. voltmeter, resistance 178,000 ohms. Scale 150 volts, equivalent sine-wave voltage.

Effect of Tube Resistance

A voltmeter circuit always has a large series resistance incorporated within the voltmeter box. Tube

resistance, therefore, not only is not a handicap but is a useful element, furnishing some of the desired resistance to the voltmeter circuit. In fact, were it not for the variability of tube resistance, it would have been desirable to use sufficiently high-resistance tubes to replace and eliminate all other series resistance. It is known that tube resistance varies with plate voltage, however, and therefore the tubes were chosen so as to make their resistance a small fraction of the total resistance of the voltmeter circuit. In the outfit described above, the tube resistance is only about five per cent of the total resistance, and therefore any little variations in the tube resistance are imperceptible in the total resistance.

Accuracy of the Flux-Voltmeter

The accuracy of the flux voltmeter in measuring the average value of any given voltage was tested both by the writer and by the Bureau of Standards and in both instances was found to be very satisfactory. Our tests consisted of (a) form-factor tests checked by oscillographic analyses, and (b) tests of application to core loss measurements.

Form-Factor Measurements

The form factor of a wave is defined as the ratio of the r. m. s. value of the wave to its arithmetical average value. Since ordinary a-c. voltmeters give the r. m. s. value, and the flux voltmeter the arithmetical average value, the form factor of a given voltage wave may be obtained by means of these instruments. The value so obtained may be checked oscillographically by computing from an oscillographic record of the wave both its effective and its average values in accordance with well-known methods. Since the flux voltmeter is graduated in terms of equivalent effective sine-wave volts, and since the form factor of a sine wave is 1.11, it follows that the form factor of a distorted wave is:

$$\text{form factor} = 1.11 \times \frac{\text{a-c. voltmeter reading}}{\text{flux-voltmeter reading}}$$

The foregoing method of test and checking was applied to seven different wave shapes obtained on different generators under different conditions of loading, with results as follows:

Items	Exciting Current Load on the Generator	Form Factor: By Oscill.	Form Factor: By Flux Voltmeter	Figures
	Per Cent			
1	20	1.21	1.231	6
2	7	1.13	1.128	7
3	30	1.148	1.149	8
4	6	1.128	1.122	9
5	55	1.18	1.18	10
6	18	1.14	1.15	11
7	2.2	1.13	1.115	12

Those who are familiar with oscillographic analyses will appreciate the great difficulty of obtaining precise results. In view of this fact, and also in view of the possible small errors of the a-c. voltmeter used, the foregoing tests may be considered excellent commercial checks on the commercial accuracy of the flux voltmeter The instrument is really much more precise than these tests seem to indicate, as the Bureau of Standards tests show.

The analyses of the oscillograms were made by a different person who had no knowledge of the form factor obtained by the flux voltmeter, in order that the observations might be unbiased.

Measurement of Transformer Core Loss

The Institute rules provide that the efficiency rating of transformer shall be based on sine-wave operation. Although certain classes of transformer losses, such as the ohmic loss of the conductor, are not affected appreciably by ordinary variations in wave shape, it is known that core loss is seriously affected by the wave shape of the impressed voltage. Since it is difficult to obtain sine-wave voltage on a commercial scale for the testing of transformers, particularly for the condition of exciting current loads which tend to distort the generator voltage, some scheme that will reduce core-loss tests to a sine-wave basis is a necessity. The flux voltmeter was developed primarily for this purpose. The graduation of the scale in terms of equivalent effective sine-wave voltage is particularly useful for this purpose.

The principle of the application of the flux voltmeter to core-loss measurement is based on the fact that if the rated excitation voltage is set by the flux voltmeter at the rated frequency, the maximum flux density in the core corresponds to the rated sine-wave voltage excitation, even though the actual impressed voltage may be badly distorted.

The maintenance of the correct rated maximum flux density in the core by this means assures that the hysteresis loss of the core will correspond to the rated sine-wave voltage, because hysteresis depends on the maximum flux density.

Aside from the hysteresis loss, a core has also eddy-current losses.

Comparing the two types of losses we find that, in general,

(a) The eddy-current loss in laminated transformer cores is much smaller than the hysteresis loss, the eddy-current loss being of the order of one-quarter of the hysteresis loss. This difference in magnitude emphasizes the much greater importance of obtaining the hysteresis loss correctly than of obtaining the eddy-current loss correctly.

(b) While hysteresis loss varies as a complicated function of the density, the eddy-current loss varies substantially as the square of the effective r. m. s. voltage. So by means of the flux voltmeter we obtain the hysteresis loss correctly, and by means of an ordinary r. m. s. voltmeter we are able to make correction for the eddy-current loss.

(c) For a given line of sheet steel, the hysteresis loss per pound may vary a great deal depending on the annealing process and handling, but the eddy-current loss is relatively very slightly affected by these factors. This means that the eddy-current loss of a line of steel may be considered fairly constant without serious error, and hence, calculated corrections applied for it, when necessary, as described below.

When the excitation voltage is set by the flux voltmeter, the desired maximum flux density, and hence the correct hysteresis loss, is obtained. If the voltage wave is distorted, however, the a-c., r. m. s. voltage will be different from the flux voltmeter voltage, and therefore the actual eddy-current voltage under test will be different from that corresponding to the rated sine-wave voltage in the ratio

$$\frac{\text{True eddy loss}}{\text{Observed eddy loss}} = \left(\frac{\text{r. m. s. voltage}}{\text{flux voltmeter reading}}\right)^2$$

A correction, therefore, has to be applied for the changed eddy loss. The method used in the tests described below was as follows. If, in a normal sample at sine-wave voltage, the percentage values of the eddy and hysteresis losses are known over the desired range of densities, then, if the eddy-current loss is left unchanged and the hysteresis loss altered and if for the test purpose the voltage is set by the flux voltmeter, it follows that the

True sine-wave core loss

$$= \frac{\text{Observed total loss} \times 100}{\text{Per cent hysteresis} + k \times \text{per cent eddy loss}}$$

where k is the square of the ratio of the a-c. voltmeter reading to the flux voltmeter reading. The relative values of the eddy and hysteresis losses in the iron sheets may be obtained from the Epstein test[2].

2. Since the preparation of this paper, an excellent method used by the Bureau of Standards has come to the attention of the writer in which no assumption whatever is made about the percentage values of the eddy and hysteresis losses but two measurements are made at different wave shapes to obtain the separation of the actual eddy and hysteresis losses. The method, of course, involves the use of either the flux voltmeter or its equivalent in some form. The method is quite simple.

The core loss test is made at two different wave-shapes, setting the voltage by the flux voltmeter. Assume that W_1 and W_2 are the observed total losses, and E_1 and E_2 the corresponding observed effective a-c. voltages. Then the true total core loss W_s for the rated sine wave voltage E_s indicated on the Flux Voltmeter is

$$W_s = \frac{W_1(E_s^2 - E_2^2) + W_2(E_1^2 - E_s^2)}{E_1^2 - E_2^2}$$

This is derived from the following basic equations:—

$$W_1 = H + W_0 E_1^2$$
$$W_2 = H + W_0 E_2^2$$

in which H is the hysteresis loss and is the same at both wave-shapes for the same flux voltmeter voltage; while W_0 is the eddy-current loss for unit effective voltage, and when multiplied by the square of the actual effective voltage gives the total eddy-current loss for that test.

The fact that the percentage eddy loss varied at different densities is to be taken into consideration by using the characteristic curve of the material similar to the sample characteristic curve shown in Fig. 13. It is to be granted that in large built cores the ratio of eddy to hysteresis is not necessarily exactly the same as in small samples, due to increased intersheet eddies resulting from the closer contact of the sheets under pressure from highly tightened bolts. Large cores, however, have also increased hysteresis loss due to pressure of bolts and other reasons, so that in large cores the ratio of eddy to hysteresis probably does not increase as

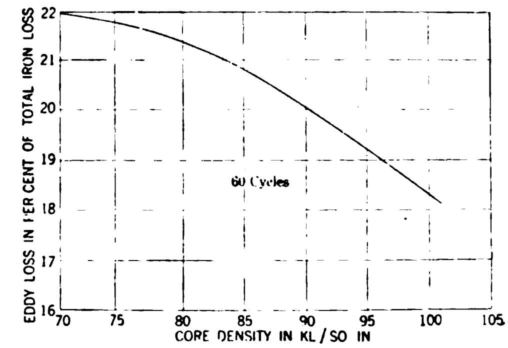

Fig. 13

much as one might expect. Furthermore, it may be shown by an example that the error that may result from this variation is not very large.

Example

Flux voltmeter setting 100 per cent rated voltage
Actual r. m. s. voltage 105 per cent rated voltage

$$k = \left(\frac{\text{r. m. s. voltage}}{\text{Flux voltmeter voltage}}\right)^2 = 1.10$$

True core loss = Observed loss

$$\left(\frac{100}{\text{Per cent hyst.} + k \text{ per cent eddy}}\right)$$

If the eddy loss is 20 per cent,

$$\text{True core loss} = \text{Observed loss} \left(\frac{100}{80 + 1.10 \times 20}\right)$$

$$= \text{Observed loss} \quad \frac{100}{102}$$

The correction for error in the eddy-current loss thus amounts to two per cent. If the flux voltmeter were not used at all and no correction applied, the observed loss would be about ten per cent in error.

To show that the assumption of a considerably different percentage value of eddy loss would not affect the foregoing result appreciably, we may suppose that

the percentage is 30 instead of 20 and recalculate the true loss. We would then have

$$\text{True loss} = \text{Observed loss}\left(\frac{100}{70 + 1.10 \times 30}\right)$$

$$= \text{Observed loss}\ \frac{100}{103}$$

Comparing this with the previous result, it will be observed that a 50 per cent error in the percentage value of the assumed eddy loss has influenced the final result by only one per cent.

Test Data. In the data tabulated below, a given transformer was tested on two or more generators of widely different wave shape, thus using the degree of agreement among the results so obtained as a measure of the accuracy of the instrument in this application. An attempt was made, of course, to make one of the wave shapes in each instance as near sine wave as possible and the other, or others, as distorted as possible. Oscillograms of wave shape are shown for each instance. Furthermore, to give to the reader an idea as to how much the wave-shape error would have amounted to if no attempt at correction for wave shape were made, the losses observed when the voltage was set by an a-c., r. m. s. voltmeter are also given for each instance.

Since in these tests the comparative values of the losses rather than their absolute values are of interest, the loss data, to facilitate comparison, have all been reduced to percentage values calling one of the readings as 100 per cent.

TABLE I

Item	Trans. Kv-a. Rating	Generator Kv-a. Rating	Per cent Load on Generator	Core Loss with Flux-volt	Core Loss without Flux-volt	Oscillo-gram Fig.
				Per Cent	Per Cent	
No. 1	1,500	500	20	100	81.6	6
	"	1,500	7	100	94	7
No. 2	1,667	500	30	100	88.5	8
	"	3,000	5	100	94.2	9
No. 3	8,000	500	55	100	87.8	10
	"	1,500	18	100.5	92.2	11
	"	12,000	2.2	99.5	98.8	12
No. 4	10,000	500	50	100.3	83	—
	"	3,000	9	100	93	—
	"	12,000	2	100	101.5	—
No. 5	28,866	1,500	45	100	82	
	"	24,000	3	100	90.8	

These data would seem to indicate excellent commercial accuracy for the flux voltmeter, inasmuch as practically the same result is obtained no matter how distorted or how pure the waveshape is. The distortion of the wave in some instances was so great (see item No. 1) that more than 18 per cent error would have existed in the core-loss measurement if the voltage had been set by an r. m. s., a-c. voltmeter.

Comparison With Other Methods

Two very similar methods have in the past been used for the purpose of reducing core-loss measurements to a sine-wave basis. It may be of interest, therefore, to present data as to how the accuracy of the flux-voltmeter method compares with theirs.

In the two older methods, use is made of a little "Standard" transformer the core loss of which has been calibrated on pure sine-wave voltage. In both methods, this "standard" transformer is excited, through potential transformers when necessary, in parallel with the power transformer under test. In one of the schemes, the voltage of the circuit is adjusted to a value such as to make the core loss of the "standard" the value corresponding to the desired sine-wave voltage. In the other scheme, the desired voltage is set by an r. m. s. voltmeter and the actual losses in both the power transformer and the little "standard" are observed. The factor which would convert the observed core loss of the little standard into its sine-wave value (known from its calibration curve) is used to convert the observed loss of the power transformer to sine-wave basis.

Tests indicated in Table I for the flux voltmeter were repeated, making corrections by these two schemes. The items in the following tabulation refer to the same apparatus and conditions as the corresponding items in Table I.

TABLE II

	Core Loss by		
	Flux-Voltmeter	Scheme No. 1	Scheme No. 2
	Per Cent	Per Cent	Per Cent
Item No. 1	100	90	91.7
	100	95	95.4
Item No. 2	100	93.3	94.2
	100	95.3	98.2
Item No. 3	100	95.2	98.8
	100.5	97.6	99.2
	99.5	99.2	102.
Item No. 4	100.3	95	96
	100	97	103.5
	100	109	111
Item No. 5	100	90.2	93.6
	100	97.4	97.4

It is interesting to note that (1) core-loss measurements made by the older schemes are influenced a great deal by differences in wave shape and that with badly distorted waves they would be very unreliable, and (2) that in eleven cases out of twelve, the losses obtained by the older methods were considerably less than those obtained by the flux voltmeter (and the one instance, in which they were more) might be somewhat doubted.

Outfits of this type have no doubt served an excellent purpose in the past, and even now, when the wave distortion is not large, they may give results which are entirely satisfactory. On the other hand, however, it appears that conditions have so changed in recent years that the average accuracy which was obtained

by the aid of such outfits five or ten years ago is not readily obtained under present conditions. The reasons for this may be seen as follows:

1. These older schemes do not attempt to maintain a known flux density in the core, but aim at drawing inferences from the losses of a small unit to the losses of the main transformer. If the two transformers were operated at the same density, this might be possible, assuming that other conditions are favorable. It is not practicable, however, to duplicate the density of the main transformer in the auxiliary "standard" core, and therefore the greater the difference in density the less reliable is the result. Scheme No. 2 described above utilizes an extra theoretical correction based on the difference in the density of the two transformers and it will be observed that it gives, in general, more correct results than scheme No. 1. Still, it is not by any means as consistent and accurate as the flux voltmeter.

2. Transformer sheet steel is constantly being improved, so that hysteresis characteristics and the eddy-current ratio are modified as time goes on, and the assumed "standard" core, even when operated at the same density as the transformer under test, ceases to be representative in a short period of progress. Even at a given time, a great variety of sheet steels are used, and it would be impossible for a given "standard" core to duplicate the characteristics of them all.

3. Although the kv-a. capacity of transformers built in recent years has steadily increased, the kv-a. capacity of generating units used for testing the core-loss of the transformers has not proportionately increased, and as a result, the core-loss load on generators in testing departments is a much larger percentage of their capacity and as a consequence the wave distortion is on the average much larger than formerly. It may be noted that generator voltage wave distortion due to transformer exciting current load is far more than that due to other loads, on account of the fact that the former draws a badly distorted current. Even in a carefully designed generator, the harmonics of the transformer exciting current will produce a large distorted regulation through the usually high synchronous impedance of the generator.

Application of Flux Voltmeter to Alternating Flux Networks

In a magnetic network, the flux density in different branches may be badly distorted, even with sine wave line voltage and sine-wave total flux. In such cases, observing the r. m. s. voltages in exploring coils on different branches would not indicate the true flux densities in the respective branches, whereas voltage observations made by the flux voltmeter would definitely and correctly indicate the corresponding densities regardless of the shapes of the waves, provided, of course, that the voltage wave does not cross the zero more than twice per cycle. This application is too simple to require any further comments.

Conclusions

1. A voltmeter, suggestively called "flux voltmeter," is described for a-c. circuits, the indications of which are proportional to the arithmetic average value of the voltage wave and hence proportional to the maximum flux density, if the voltage is the reactive drop corresponding to the flux.

2. The primary application of the instrument is to the reduction of the core-loss measurements of transformers to sine-wave basis. The method is to set the desired value of the voltage by means of this instrument, in which case the maximum flux density in the core corresponds to the desired sine-wave voltage, even though the impressed voltage is badly distorted. Methods are indicated for taking into consideration the error in the eddy-current loss. Accuracy of the meter in this application is believed to be within one-half of one per cent.

3. In comparison with other and older schemes for the reduction of core loss to sine-wave basis, it is noted that the flux voltmeter has the following advantages:

a. Its results are unaffected by the rated flux density of the transformer core.

b. It is unaffected by the quality of the core material used.

c. It is applicable to all commercial frequencies.

d. In general, core losses obtained by other schemes are smaller than those obtained with the aid of the flux voltmeter.

e. The flux voltmeter puts practically no load on the instrument transformers.

4. The flux voltmeter may also be used for exploring alternating flux networks.

5. The only limitation of the flux voltmeter seems to be in those instances in which the voltage wave crosses the zero line more than twice per cycle. Such distortions of voltage waves, however, are so rare commercially that it is difficult to conceive of encountering them in practical core-loss tests.

The author is indebted to Mr. C. A. Read for the taking and analysis of the oscillograms; to Messrs. M. G. Newman and A. Boyajian for advice in the progress of the investigation; and to Mr. L. de Nagy for assistance in making the tests.

Excellent Seminars for Practising Engineers:

A Challenge to Engineering Teachers

BY EDWARD BENNETT[1]

Fellow, A. I. E. E.

STATED in broad and comprehensive terms, the *primary responsibility* of the engineering colleges is for the development of four groups of men; for engineering work namely,

a. Undergraduate students
b. Graduate students
c. Practising engineers
d. Engineering teachers.

The responsibility of the colleges of engineering for the first two groups is evident and is not discussed in this paper. On the other hand, the possibilities of educational activities with the third group are just beginning to appear on the educational horizon, and the question naturally arises as to the grounds for listing such activities as a responsibility of the colleges.

Two considerations seem to warrant our regarding educational activities with practising engineers as responsibilities, or at least as promising fields of service for the colleges of engineering.

First. An appreciable percentage of practising engineers and of engineering teachers contend that an adequate foundation for an engineering career cannot be obtained in the four-year course. They advocate the plan of keeping the engineering students within the college walls for an additional year or two. If this contention is well founded, but if, for one reason or another, it is not deemed best to require engineering students to remain on the campus for a fifth year, it seems logical to consider the extent to which it may be feasible to carry the college to the young engineer in practise.

Second. It is a commonplace that most engineers (and this applies equally to all of the professions including the teaching) are unable to keep abreast of the rapid scientific developments in their field, and as a result are not in a position to do clean cut effective work. There would seem to be a distinct opportunity for the colleges to be of service to engineers whose training along scientific lines may have been quite adequate at the time they entered practise but who have come to feel the need of a fundamental re-examination of certain fields.

In view of these considerations and others to be presented later, it would seem that the engineering colleges should, by trial, determine the feasibility and desirability of conducting in nearby engineering centers *seminars* or *conferences* of one or more of the following types for practising engineers.

Type A. Advanced studies of the kind given in residence in postgraduate work; studies n mathematics, physics, engineering subjects, etc.

Type B. Seminars dealing with recent developments, designed to enable he older graduates to keep abreast of the scientific advances.

Type C. Seminars for the discussion, in the light of fundamental theory, of

a. Allied or common research problems
b. Allied or common design problems
c. Allied or common operating or manufacturing problems

A brief sketch of two seminars for practising engineers sponsored by the University of Wisconsin may be of interest.

Two years ago a group of technical graduates of ten or more years' experience, and all in responsible positions in the metallurgical industries, requested the opportunity to work for an advanced degree and to carry on this work in Milwaukee, 85 miles east of Madison, the seat of the University. Since an experimental research in some technical subject would be a necessary part of the proposed graduate work, the proposal was welcomed because it held promise of opening the way to a very desirable type of cooperative research between the engineering industries and the college. I refer to the type of research in which problems are not brought to the college laboratory to be solved, but, in which the facilities and views of the college, are carried to the industrial laboratory or the engineering office, and in which the primary function of the college in research—namely, the training of men in engineering research—is emphasized and is given wider scope. The positions held by the eight men in this group are as follows:

Works Manager of the Milwaukee Steel Foundry Company
Vice-president of the Badger Malleable Company
Works manager of the Globe Electric Company
General superintendent of the Federal Malleable Company
Metallurgist of the Federal Malleable Company
Metallurgist of the Glancy Malleable Corporation
Metallurgist of the Vilter Manufacturing Company

The *significant* thing about the list is that these men are in competing industries and are cooperating in a highly effective manner in the solution of their common problems.

During the past two school years this group has met in Milwaukee each Friday evening for a conference extending from 7:30 to 10:30, or later, with Professor R. S. McCaffery or other members of the Mining

1. Professor of Electrical Engineering, University of Wisconsin, Madison, Wis.

Presented at the A. I. E. E. Regional Meeting of District No. 5, Madison, Wis., May 6-7, 1926.

or Metallurgical Department.[2] On Saturday, the professor visits one or possibly two of the members of the seminar at his plant or laboratory and discusses the research project which is under way. The research projects, which were selected by the men themselves, are as follows: A study of the reactions which take place in a basic steel furnace; an electrical method of rapidly determining the quality of the molten metal in malleable air-furnaces; the determination and comparison of the heat balances of hand-fired, oil-fired and pulverized-coal-fired malleable furnaces; the effect of silicon and manganese on the properties of malleable iron; and the study of the reactions of combustion in a malleable furnace for the purpose of obtaining greater accuracy of control of the finished product.

In the conduct of a seminar for the discussion, in a fundamental way, of allied questions, the first and most difficult problem which presents itself is that of getting the members of the group to talk the same technical language. This requires a review of the experiments, concepts, postulates, definitions, sequences and principles which underlie the branch of science with which the group is concerned. Accordingly, the Friday evening conferences during the first five months were devoted mainly to a review of the fundamentals of physical chemistry applied to metallurgy. This involved a study of equilibriums in chemical and metallurgical reactions and of equilibrium diagrams, the application of the phase rule, mass law, atomic structure and the velocity of reactions.

The impression made by this work is indicated first, by the fact that some of the concerns listed above have established fellowships at the university in order that the holder of the fellowship might collaborate with the member of the seminar by carrying on supplementary researches at the university, and second, by the fact that some 26 grey iron foundaries operating in the Fox River Valley have formed a local association to carry on and finance cooperative research at their own plants and in Madison; a similar group of about 20 grey iron foundries in Milwaukee is organizing to carry out a program of the same kind.

The second seminar was organized at the solicitation of electrical engineers in Milwaukee. The men in this group, which started with 18 men and ended with 13, are electrical engineering graduates with from two to six years of experience. During the past year this group met in Milwaukee each Thursday evening with a professor from the university for a seminar of the A type,—a seminar for the discussion of *transient phenomena and waves in electric circuits*. This course was largely a mathematical development of circuit theory, with, of course, constant illustrations of the application of the theory to transformers, generators and power and communication systems. As a result of the experience of the men with this seminar, courses of a similar nature have been solicited and will be given during the coming year. At least one industrial organization has under consideration plans for meeting all or part of the tuition expense of its employees who successfully complete courses of this kind.

The Significance of the Seminars to Industry

It may be well to list the significant possibilities to industry of seminars conducted by the engineering colleges for men engaged in engineering practise. They are:

Such seminars, if available, will enable some graduates of four-year engineering courses to obtain a more thorough scientific training for engineering work.

Seminars of the B type might be used to serve as the line of communication between the advance scientific workers and the main body of engineers, or to enable engineers who, in the press of work, have lost touch with certain allied fields, to "come back" in these fields.

During the apprenticeship period of the first few years after graduation, many engineering graduates slip in their grasp of mathematical methods and analysis. A course of the A type, if pursued during this period, should be of value in more firmly fixing these methods and in warding off the mental slump which frequently occurs during a depressing apprenticeship period.

That both industry and engineering education have much to gain by closer cooperation in engineering work, particularly of the research type, needs no argument. The kind of cooperation which has received more attention in the past is that in which certain research problems have been taken to the college laboratory for solution. By seminars of the C type, the views and the methods of the college are carried to the industrial laboratory, and the primary function of the college in research—namely, the training of its own staff and of its students in research—is made more apparent and is given wider scope. More research for engineering teachers both in the college and in industry is badly needed.

Engineering seminars sponsored by associations formed by the smaller industrial enterprises for the fundamental examination of their common technical problems may be a means by which the smaller enterprises with their desirable social characteristics may retain a place in the sun by the side of the modern corporation.

One of the barriers in the way of more effective cooperation between the industries and the state colleges results from a difference in the social philosophies in the two fields of action, namely, in the industrial field and in the professional field in general, or the teaching field in particular. In the educational and scientific field, the rewards and increased opportunities come from the sharing and free disclosure of all

2. For a more detailed statement of this work, see the paper by Professor R. S. McCaffery entitled "Research Cooperation between University and Industry," Canadian Inst. of Min. & Met., Vol. XXIX, 1926.

achievements which result in the advancement of knowledge. In the industrial field, the careful guarding of trade secrets is still regarded in many industries as highly essential, and the obtaining of exclusive rights through patent control is frequently the main consideration which leads to the support of research work. These conflicting demands—for the unreserved disclosure and for the exclusive use of knowledge—are the greatest barrier in the development of cooperative relations in those fields in which important improvements and inventions are likely to be made.

The most promising sphere for the organization of seminars for the consideration of allied or common engineering problems is with associations of manufactures or of public utilities. In this case it would seem quite possible to formulate a policy with reference to the granting of preferential but not exclusive patent rights which would harmonize the views and rights of all parties in the enterprise. The essential features of such a policy are outlined in Sec. VIII and IX of Circular No. 9 of the Engineering Experiment Station of the University of Illinois, entitled "The Functions of the Engineering Experiment Station of the University of Illinois," by C. R. Richards.

Not the least among the possibilities for good of these seminars is the possibility that the advantages of cooperation may be shown to be so great that it may become obvious that the thing to do is to modify those features of the patent law which make the existing law a barrier to cooperation.

The type of seminar which holds the greatest promise of achievement is a seminar of experienced engineers from the same or allied fields who have come together to conduct a critical analysis of certain cases or certain lines of engineering practise. It may seem like presumption to suppose that men from the colleges can be of much service to such a group. The presumption is tempered somewhat by the consideration that the introduction of a foreign body into saturated solutions frequently initiates crystallization. In a group of experienced engineers, the man from the college may at least play a role not unlike that of the foreign body in the chemical solution. The achievements should come mainly from the contributions of the practitioners to the conference. Judgment should not be passed as to the relative contributions to be expected, however, until we have considered the significance of these seminars to the engineering teachers.

Significance of the Seminars to Engineering Education

The fourth responsibility of the engineering college is for the development of engineering teachers. One of the strongest arguments for sponsoring seminars for practising engineers is the part which these seminars will play in the development of engineering teachers.

The seminars will compel and will reward a broader and a more thorough training than is common in the teaching ranks today.

They will afford greater opportunities to determine the adequacy, the relative importance, and the real significance of the principles and the methods taught to undergraduates.

They will make teaching attractive to a wider range of engineers by making it possible for men in teaching to have closer contact with engineering practise.

They will help to supply one of the greatest needs of the engineering colleges of the country; namely, the atmosphere, the spirit and the prestige which will accompany more examples of engineering work in progress or carried to a successful conclusion in the colleges or by the engineering teachers.

The opportunity to develop these seminars comes to the teaching profession as a challenge; a challenge because the task is no light one but one beset with difficulties and even with an element of danger to undergraduate instruction; but above all, a challenge because the acceptance of the opportunity means the acceptance of a goad and the acquirement of an incentive which will bring the work of the engineer and of the engineering teacher to a higher plane.

WELDING LARGE METAL STRUCTURES

The American Bureau of Welding, 29 West Thirty-ninth Street, New York, N. Y., is planning an extensive investigation of welded steel structures. James H. Edwards, assistant chief engineer of the American Bridge Co., 71 Broadway, New York, N. Y., one of the directors of the American Bureau of Welding, is interested in this method of fabrication, which may have many advantages over riveting.

Electric arc welding was used by Mr. Edwards' company to fabricate some steel plates in order to determine the difficulties which might arise in using this process. The result was a plate girder 15 feet long, having a web plate one-half inch thick and 24 inches deep. The flanges were 12 inches wide, one $1\frac{3}{4}$ and the other $1\frac{7}{8}$ inches thick. A cover plate $9\frac{1}{2}$ inches wide and nearly as thick as the flange was used on the top and the bottom flanges. Nine stiffeners on each side were welded to both flanges and the web.

To determine the strength of this structure, particularly whether or not the welds were satisfactory, it was tested by the Bureau of Standards in cooperation with the American Bridge Co. The Olsen hydraulic machine, having a capacity of 10,000,000 pounds, was used, loading the girder at the middle of a $13\frac{1}{2}$-foot span.

It was gratifying to find that the maximum load was somewhat greater than this estimate, and that the welds connecting the web to the top flange failed at the ends only after the web was buckled and the girder had deflected several inches.

The investigation will enable an engineer to design safe welded structures. It is probable that a saving in the cost of steel structures will result.

Discussion at Midwinter Convention

THE CALCULATION OF MAGNETIC ATTRACTION[1]
(LEHMANN)
NEW YORK, N. Y., FEBRUARY 11, 1926

C. O. Mailloux: This is another of the papers of the kind which, like one by Mr. Fortescue[2] published some years ago and one by Mr. Rice[3], written more recently, serves to advance our knowledge of ways and means of attacking problems that have baffled all others before these authors, and at the same time gives us very interesting evidence of the fact that the methods of mathematical treatment of previous generations—say of the days of Maxwell, Kelvin, Mascart, Helmholtz, etc.—are still capable of giving magnificent results. Mr. Fortescue, in an epoch-making paper, showed the valuable use that can be made of the principles of the *potential energy function* and of their application to the discussion of equipotential surfaces, etc., as a means of mapping out the field of electric force around insulators that are subjected to high electrostatic stresses. Those who may have had doubts at that time in regard to the utility of the study of the potential function as a preparation for the analysis of phenomena in fields of force, and were disposed to look more sympathetically upon the more "modern" methods devised or elaborated by Bjerknes, Lorenz, and others, found that their fears in regard to the "staleness" of the older methods were not wholly well founded. What Mr. Fortescue did was, in a sense, an extension of Maxwell's work, and his diagrams of lines of electric force in electrostatic fields show at least a family resemblance to some given in Maxwell's treatise. Mr. Rice's able paper furnished further valuable evidence of the great usefulness of this method of attack on seemingly difficult problems of like character.

In the present paper, we have the very interesting case in which the theory and the principles of the potential function enable the author to perform an entirely new *tour de force* that would have done credit to Maxwell himself, showing such a simple and practical way of "surveying" and *appraising* the magnetic force in an air-gap that we wonder how such a clever expedient has remained so long undiscovered. Every student of the theory of the potential function knows that the concept of the "tube" of magnetic force, even though it may be after all only a figment of the scientific imagination, does account, in a very simple way, for differences of magnetic density and distribution that are often impossible to describe by any other method, notably by the measurement or expression of variations in magnetic density in different parts of the magnetic field. It was an inspired idea of the author to decompose the magnetic field in the air-gap into *elemental tubes of magnetic force*, with boundaries (or envelopes) enclosing spaces in which the magnetic flux is constant. This amounts virtually to the same thing as finding paths across the air-gap where the magnetic density may be treated as if it were constant. In this way the author found a means of getting across the air-gap without having to stop midway to rearrange and readjust the magnetic density; and with the aid of the principle of "solenoidal distribution" and of equipotential surfaces, all of which is a part of the theory of the potential function, he had the absolute certainty of being able to get across safely before he started. The only problem that remained to be solved was that of making "landings" at both ends of the path followed in crossing the air-gap through a tube of magnetic force when that path is not exactly straight across, *i. e.*, when the tube of magnetic force is not "normal" to the surface of the poles or other ferromagnetic portions of the magnetic circuit on the two sides of the air-gap. The author solved that problem in the well-known, simple way, familiar to mathematicians, of replacing any contour line by an equivalent broken line, on the principle that a circle may be regarded as a polygon of an infinite number of sides. Now, the fundamental fact that makes this method rigorous as well as interesting and effective is the well-known principle that whenever a potential energy function *exists*, as is the case in an air-gap, the *initial* and the *final* stages of the potential developed (which in this instance is magnetic potential; that is to say, the conditions determining the *strength* of the physical *bond* between the two edges of the air-gap) are really independent of the locus of the path through which the tube of force is "laid." Indeed this far-reaching generalization, a great achievement and precious inheritance from the mathematical physics of previous generations, was the key that unlocked the secret of the wide power and range of the method and that inspired confidence in it by showing how far it can be relied upon.

The paper deserves to be regarded as a pathfinder, pointing the way to new and really wonderful applications of old but still "up-to-date" and most effectual methods of attacks on difficult problems. It is seen that the figments of the scientific imagination, to which I have just referred, can play a most important role and can lead to highly useful concrete results as they did in Mr. Fortescue's paper. As in that case (aside from the useful practical applications) the result is a contribution to general theory and will add value in a permanent way to the TRANSACTIONS of the Institute.

The paper may not prove as easy of perusal and comprehension as might be, because some of the ideas in it are presented somewhat tersely and are not, therefore, placed within as easy reach of the ordinary reader as might have been, perhaps, had the author realized the desirability of so doing. The mathematics are simple enough; in fact, they are elementary to those who have studied the theory of the potential energy function and mathematical physics to even a slight extent, although they may seem abstruse, imposing, and forbidding to those who have not done so. The paper really deserves to be made accessible to a very large constituency. This could have been done easily by taking a little more space for the presentation of the mathematics in slightly more "dilute" form. The objection most often made to papers of this type is, indeed, that their authors do not sufficiently recognize the importance of making them entirely clear to those who do not know or remember as much as they do themselves about the "short cuts" in mathematical transformations and demonstrations. A few notes given in an appendix, clarifying the more abstruse portions, would help greatly to remove the impression that the paper is merely a "high-brow" product which will, or can, interest only mathematical students and experts. In this respect, however, the paper will be found to be not nearly so formidable as it may look. Moreover, those who are interested in this general subject will find such additional information and elucidation in other articles by Dr. Lehmann which have appeared in the *Revue Générale de l'Electricité*; notably in the article published in the numbers of July 12 and 19, 1924. This was written at about the same time as the present paper and covers substantially the same ground, but does it in a more detailed manner, and also throws full light upon the theoretical considerations which the author kept in mind and which underlie the methods described in the paper.

J. Slepian: It is usual to derive the forces acting on material bodies in a magnetic field by starting with the principle of conservation of energy, calculating the electrical energy input and the increase in magnetic energy, and assuming that the difference in these quantities gives the work done by magnetic forces on bodies which are displaced. This is the procedure followed by Doherty and Park in their paper.[4] Mr. Lehmann, however,

4. *Mechanical Force between Electric Circuits*, by R. E. Doherty and R. H. Park, A. I. E. E. JOURNAL, March, 1926, page 231.

starts with Maxwell's expression for the stresses in a medium in which a magnetic field exists.

In the time of Maxwell, the great program of physics was to explain all phenomena mechanically. Therefore it was very natural to try to explain the transmission of force over distance through the mediary of a magnetic field by a mechanism similar to that by which force is transmitted mechanically through material bodies, namely by a system of mechanical stresses. Maxwell was led to believe that the following system of stresses would account for the mechanical forces in a magnetic field: a tension equal to $H^2/8\pi$ per sq. cm. across any surface perpendicular to the lines of magnetic force, and a pressure equal to $H^2/8\pi$ across any surface parallel to the lines of magnetic force.

In applying these stresses to determining the forces on material bodies, however, a difficulty arises, for these stresses are supposed to exist in empty space or in the ether as well as in material bodies. And since the ether pervades all material bodies, we cannot tell how much of the stress at any point acts on a material body there, and how much is limited to the ether. Maxwell resolved this difficulty to some extent by showing for a stationary magnetic field that although these stresses do not give the actual ponderomotive force at each and every point of a material body, when integrated over a closed surface, they do give correctly the total ponderomotive force on all the material bodies enclosed in that surface.

Herein lies one of the difficulties which I have found in trying to follow Mr. Lehmann, for apparently he integrates the stresses over a surface which is not closed. Such a procedure if carried out, for example, over a portion of the surface of a wooden body would give a resultant force, and yet we feel quite sure that no such mechanical force exists on any portion of such a body. If the integration is carried out over the whole surface of the body, the correct zero resultant is obtained, but not if the integration is limited to a part of the surface.

It is easy to see that if a body has infinite permeability, then integration over any portion of its surface will give correctly the mechanical force on that portion, and it so happens that the example which Mr. Lehmann has worked out is for a body with infinite permeability. But if the method is applicable to the case of finite permeability, it seems to me that some further justification is necessary. I would be very happy if Mr. Lehmann could clear up this point for me.

The formula which Mr. Lehmann has obtained is similar to that obtained by Doherty and Park by considering displacement of a magnetic body under constant flux, and I presume is intended to apply also for the case of saturation. However, Mr. Lehmann does not limit himself, as do Doherty and Park, to special magnetic circuits where the flux density is constant in the air gap during the displacement, but suggests that the result is general. This is a question of very great importance and I therefore considered it worth while to try to derive this result from the principle of conservation of energy. In so doing I ran upon a difficulty which Mr. Lehmann hints at in his paper but which I have not been able to surmount. Perhaps Mr. Lehmann can show how to take care of it.

I used the following artifice: In the magnetic system under consideration, assume that all currents which are flowing are in resistanceless circuits so that no impressed voltages are required. Now assume that with the bodies in the position for which the force is to be calculated, all bodies which are subject to magnetic saturation are made infinitely conducting. No change in the magnetic force results from these hypotheses. Now let one of the saturating bodies be displaced a small amount, Δx. Then currents are induced in the various circuits and conducting bodies, the magnetic field changes, and work is received by the moving body. Now, since the electromotive forces are zero, there is no input of electrical energy. Hence the work received by the moving body must be equal to the decrease of magnetic energy. Since the saturating bodies are by hypothesis infinitely conducting, there will be no change in the magnetic field within them at any point, so that the magnetic energy in their interior remains constant. Hence the whole change in magnetic energy is external to the saturating bodies. This change in the external magnetic energy may be resolved into two parts. First we may consider the change which would take place if the energy density at every point remained constant, so that the motion of the saturating body merely changed the boundaries of the external field. This change may be determined by multiplying the energy density at each point of the surface of the body by the normal component of the displacement of the surface and integrating over the whole surface. This change in magnetic energy considered by itself leads directly to Lehmann's formula. However, there is the second part of the change in magnetic energy which must be considered; namely, that due to the change in energy density at the various points of the field. If ΔW is the change in magnetic energy density at any point of the field, resulting from the displacement of the saturating body, then the volume integral,

$$\int\int\int \Delta W \, dx \, dy \, dz$$

taken over the whole external field gives the other part of the change in magnetic energy.

If Mr. Lehmann's result is correct, this integral must be equal to zero. However, I have not been able to establish the fact that this is necessarily the case and would like to ask Mr. Lehmann if he can suggest how this is to be done.

R. H. Park: Two methods of calculating the mechanical forces due to magnetic attractions have been presented at the 1926 Midwinter Convention; namely, a method of calculation based on analysis of flux through circuits, and a method based on the analysis of stresses acting at each point of a closed surface bounding the volume on which the force is to be calculated. Both methods have special fields of application in which they are of particular value. In the formula

$$F_l = \frac{\phi^2}{8\pi} \quad \frac{\delta R_o}{\delta l}$$

of the paper by Dr. Lehmann, he has given a useful simplification of the known methods of calculating force on the basis of stress acting on bounding surfaces. For this particular result and also for his introduction of the general method of calculating force from stresses on bounding surfaces to problems of practical character, Dr. Lehmann deserves much credit. Without wishing to detract in any way from the practical value of Dr. Lehmann's paper, I should like to mention a few considerations which may deserve attention.

In particular, the application of formula (1) of the paper to problems in which saturation exists both within and without the volume in which the force is to be calculated may be open to question. In his "Electrical Papers," Volume I, pages 542 to 553, and Volume II, pages 543 to 574, Oliver Heaviside shows definitely that formula (1) applies in the case of saturation when there is no saturation outside the region on which the force is to be calculated. He also gives a formula which applies in the more general case and in the interior of saturated regions. This result would indicate that formula (1) of the paper was correct in application in the case when there is iron both within and without the region on which the force is to be calculated, if the intersurface does not pass through saturated material. The arguments employed, however, in establishing these results are not entirely clear since no explanation is given that the assumptions on which the proof is based are in accord with experimental facts.

In regard to Dr. Lehmann's definition of his reluctance R_o, it may be pointed out that the determination of this reluctance requires a previous knowledge of the distribution of the field in the region under consideration. It therefore depends on the character of the medium at points outside of the particular

region under consideration. Also there is a difference between the term $\frac{\delta R_0}{\delta l}$ and the ordinary total derivative of $R_0 \frac{d R_0}{d l}$. The derivative $\frac{\delta R_0}{\delta l}$ corresponds to a change in δl with the flux density and direction of the field fixed at the bounding surfaces.

C. O. Mailloux: With reference to the remark made by two of the discussers that the method is of direct application to questions where the permeability is independent of the field, that statement is brought out in the paper itself. The author concedes that point and there is no question about it. At the end he does refer to the fact that the formula can be completed by a saturation factor, but there is no detailed reference given to that, so we may assume that he didn't feel sufficient confidence in that new development to introduce it into the paper.

The inquiries made by one of the speakers are partly answered in the paper itself; notably where the author speaks of a complete integration around a circuit and counter-balancing effect produced by the integration of the second part of the circuit that is already shown diagrammatically in Fig. 10.

In regard to the detailed analysis of the formula, he preferred the purely practical method of finding what allowance, if any, could be made for the variation of magnetic field, when the length of the air-gap is increased or decreased, by calculating two cases where it has been done, proceeding with one from the inside and the other from the outside. He thus finds the difference between the two is within one per cent.

Now, for the cases with which he was interested in dealing, that error certainly is sufficiently small and, while the theory might be very interesting in a question of splitting hairs, it is not of immediate concern in connection with the present paper. I hope, however, that the author will be given an opportunity to explain himself to any such extent as he may deem necessary.

In the paper he does not mention the potential function, but anybody at all familiar with the subject knows that it is based upon that. One of the characteristics of potential function is that it goes into no speculation as to action at a distance. That may be the difficulty encountered by the gentleman. It is independent of all speculations as to the intervening medium or the actions at a distance. Had the author wished to go into it, he would have to begin by discussing the physics and mathematics of a tube of force, itself. He has assumed that as implicitly as one would assume the multiplication table in mathematics. Hence, if that is accepted as a fact and the explanation is sought for in some other books on mathematics, it seems to me a great many of the difficulties will disappear.

Th. Lehmann: I am indebted to Mr. R. H. Park and to Mr. J. Slepian for giving me, by their remarks, an opportunity to define further the scope of my paper. I also thank Dr. Mailloux for already having replied in part to their discussions.

My A. I. E. E. paper is a condensed summary of articles which have already appeared in the *Revue Générale de l'Electricité*, (Paris), July 12th and 19th, 1924, in which I made explanation (especially in paragraph VIII) of the fictitious character of Maxwell's stresses and pressures. In writing the A. I. E. E. paper it appeared to be desirable to leave out that paragraph and certain others to avoid lengthening it too much. In saying in the introduction to my paper, however, that I was taking into consideration only the resultant magnetic effort produced in a ferromagnetic body entirely surrounded by air, it seemed to me that there could be no doubt that the formulas (**1**) and (**4**) should be integrated along the *whole* of surface S in the body, especially since the letter S was added at the bottom of the integral sign to show that a *surface-integral* was intended.

Maxwell himself observed that the vectorial function, $P/8\pi$, which appears in the integral expression, is of fictitious character, inasmuch as it represents magnetic effort per unit of surface. The fact of having shown how this function may be evaluated and used in the determination of the true resultant does not at all imply that a real entity is attributed to the elemental effort per unit of surface, $P/8\pi$.

This point now having been made clear, I wish to assert that, for any closed surface of integration, the formula

$$F = \int_S B_{2\alpha}^2 \, d\, S, \qquad (\mathbf{4})$$

is equivalent to formula (**1**), the range of validity of which seems to have been determined previously by Oliver Heaviside. In any case, formula (**4**) gives exactly the *resultant* magnetic effort exerted upon a ferromagnetic body, C, having a surface, S, entirely surrounded by air, whether the permeability of the body be variable or not and even when the body, C, has hysteresis[5]. In the external medium, (the surrounding air), there may be other saturated ferromagnetic bodies and also some currents, provided the whole of the surface, S, of the body, C, be separated from the other ferromagnetic bodies by an air-zone.

Here I shall go no further than to state that I have given elsewhere (in the *Revue Générale de l'Electricité*, 1925, Vol. XVII, p. 167) the demonstration of the validity of formula (**4**) for a body, C, that is saturated but free from hysteresis, this being done by means of a schedule of the virtual potential energy involved, obtained by applying the theorem of W. Thomson. Another demonstration which does not use this theorem but which also includes the case where the body C is not free from hysteresis will appear shortly in the *Revue Générale de l'Electricité* (in September or October, 1926).

The same conditions, as regards validity hold also in the case of the formula

$$F_l = \frac{\phi_0^2}{8\pi} \; \frac{\delta_{R0}}{\delta l} \qquad (\mathbf{7})$$

If, for the value of the flux, ϕ_0, we take the circumflux[6] and, for the reluctance, R_0, the value obtained by means of the formulas (**3**) and (**3'**), with that flux, then for example formula (**7**) will give the *true resultant* in the direction of δl, on the armature of a dynamo. Of course, $\delta R_0/\delta l$ is the *virtual* derivative of that reluctance, and, as pointed out correctly by Mr. Park, it should not be confused with the ordinary total derivative, $d R/d l$. Naturally the formula can be applied also to each pole or to each magnetic circuit in turn. The respective magnetic efforts thus obtained should then be considered as being component portions of the total magnetic effort, and their vectorial sum will give the *true resultant effort* rigorously, whether the magnetic circuits be saturated or not.

The effort actually exerted upon a pole or upon a tooth can be determined in the manner which I have already indicated in the *Revue Générale de l'Electricité*. When there is no deformation (*i. e.* when the magnetic effort produces no change in geometrical figure) in the pole and in the tooth, the method of procedure is as given on page 101 of the issue of July 19th, 1924, in paragraphs VI and VII; and when deformation is produced, the method corresponds to the formulas (**9**) and (**11**), as given in the April 4th, 1925 issue. If Mr. Slepian will kindly refer to these earlier papers, I dare say that he will recognize the fact that the fictitious character of Maxwell's stresses and pressures had not escaped me in the least. But all this was quite outside the scope

5. It should be stated that A. Liénard has already pointed out (in the *Revue Generale de l'Electricite* of October 20th 1923, p. 563) that the formula (**1**), when integrated on the *air* side along the surface of a ferromagnetic body with hysteresis gives exactly the resultant magnetic effort. Moreover, A. Guilbert has given a very satisfactory experimental confirmation of formula (**7**) in his paper (Paris, 1926) which was published as a supplement to the Bulletin of the Société Francaise des Electriciens for January 1926.

6. That is to say, the absolute sum of the fluxes per pole which are common to all the poles; this, in the case of an armature which is not excentric in the magnetic field, is the same as the product of the number of poles and the flux per pole.

of my A. I. E. E. paper; in that I intended to take into consideration only the effort exerted upon a ferromagnetic body that is entirely surrounded by air.

The evaluation of the virtual derivative of the reluctance of the air, $\delta R_0/\delta l$, should be made by reference to Fig. 4 to 7A whenever the boundary air-surfaces may be considered equipotential, of which condition the reader is duly warned at the beginning of paragraph V (by the condition $\mu = \infty$ in the iron). In the case of superficial saturations of the pole-pieces of the armature, up to B = 18,000 c. g. s. (or $\mu > 100$), the departure of the lines of magnetic force passing through the air from the orthogonal direction with respect to the boundary surfaces, is still scarcely noticeable, and the methods described are still applicable with a degree of precision that is amply sufficient for practical purposes. The case given by way of example for a half-pole, should, naturally, be extended to all the poles when the magnetic field is excentric; this can be done by making δx coincide with the direction of the axis of excentricity. When the field or the armature is saturated to such a point that the lines of magnetic flux are no longer normal to the boundary surfaces, it becomes necessary to determine the segments σ' and σ'' along the whole of the air-surface for each tube of magnetic flux in accordance with the method indicated in Fig. 8; and, in that case, by following the external contour of the armature, we have

$$F_x = \frac{\phi_0^2}{8\pi} \sum \frac{1}{m^2} \left(\frac{1}{\sigma'} - \frac{1}{\sigma''} \right) \qquad (10)$$

In making the summation along a portion of the poles and of the outermost lines of force of the flux per pole that is common to both parts of the magnetic circuit, it is necessary to add, for each outer line of force, a term[7] which corresponds to

$$\frac{\phi_0^2}{8\pi m_n^2} \left(\frac{1}{\lambda_1'} + \frac{1}{\lambda_2'} \right).$$

As I pointed out in the *Revue Générale de l'Electricité* of July 19th, 1924, at the end of paragraph VIII, the elemental contributions per tube should be considered fictitious for the same reason as in the case of Maxwell's effort per unit of surface, $P/8\pi$, in formulas (1) and (4).

As to the last question asked by Mr. Slepian, it will be found to be answered fully in the article already mentioned, which is to appear soon in the *Revue Générale de l'Electricité*, and in which the magnetic attraction between bodies that are saturated and that also have hysteresis is deduced from a schedule of the actual energy involved, in a virtual displacement, without abstractions or hypotheses.

For the convenience of those who do not have ready access to the files of the *Revue Générale de l'Electricité*, a brief reference to the article published in July, 1924, may be useful.

As stated in the preface of that article, the following points are considered in it: (1) simplification of the physical formula for attraction; (2) definition of magnetic reluctance when the field is bounded by non-equipotential surfaces; (3) calculation of the virtual variation of the reluctance due to any displacement whatever of the limiting surfaces; (4) demonstration that the magnetic effort between two bodies depends only upon their common flux, ϕ, and upon the virtual gradient of its air-reluctance, R_0, and that the formula

$$8\pi F_l = \phi_2 \, \delta R_0/\delta l$$

which gives the attraction in any direction whatever, l, is as exact and general as the formulas of physics; (5) direct deduction of the attraction from the lines of flux of a magnetic figure without having to determine the components of the field; (6) evaluation of the local magnetic effort exerted upon a tooth or pole that is inserted in a groove, when the permeability is a function of the field.

The article contains nine sections, of which the last four include material that supplements the A. I. E. E. paper, which latter, as a matter of fact, was submitted to the Meetings and Papers Committee early in 1924, or before the publication of the articles in the *Revue Générale de l'Electricité*. In Sections VIII and IX, many points in regard to the validity and applicability of the formulas are made clear. Section VIII perhaps, ought to have been included in the paper. It is reproduced here (translated) with equation (13), taken from another part of the paper which could not be understood unless reproduced.

(Extract from *Revue Générale de l'Electricité*) (July 19, 1924)

"VIII. DIGRESSION. The formulas of physics for magnetic attraction are not much use in practise. Are physical hypothesis at all responsible for this? It cannot be denied that at first glance our sense of practical intuition, refined by the concept of the magnetic circuit, finds it difficult to admit the figment that excludes all disturbance in the magnetic field during a virtual displacement. But that figment, although it may lead to a state of disequilibrium, can be justified by the theorem of Thomson applied to two neighboring states of distribution, one of which corresponds to a minimum of potential energy."

It may, perhaps, be better not to look so far but simply to attribute the above reflection to the dilemmas that one meets when Maxwell's stresses are applied to surfaces which are not closed. An example will make the difficulty more clearly apparent.

Let us suppose a mass of soft iron of constant permeability, μ, and free from all internal currents. The effort exerted upon such a body in an air medium of permeability, μ_0, may be evaluated according to formula (13) in either of two ways. We have

$$\int_s P \, d\,S = \int_v \{2\,H \operatorname{div} B - H^2 \operatorname{grad} \mu - 2\,(B, \operatorname{rot} H)\}\, d\,v \qquad (13)$$

The term on the left-hand side is a surface-integral which is equal to (3), or

$$F = \frac{1}{8\pi} \int_s \{\, 2\,H\,(B, N) - N\,(H, B) \,\}\, d\,S \qquad (3)$$

The term on the right-hand side in (13) is a volume-integral which is obtained by the aid of the generalized theorem of Ostrogradsky (See Vaschy, *Théorie de l'Electricité*, 1896, p. 66).

The first of the two ways of evaluation is by means of the surface-integral,

$$8\pi F = \int_s P_0 \, d\,S \qquad (25)$$

and the second is by means of the volume-integral

$$2\pi F = -\int_V H^2 \operatorname{grad} \mu \, d\,v \qquad (26)$$

Since the permeability, μ, has been assumed to be constant, we have, in the iron, grad $\mu = 0$, except at the surface S, where grad $s\,\mu = N\,(\mu - \mu_0)$. For each surface element, $d\,S$, the volume integral, it will be recalled, will receive the contribution

$$(P_0 - P)\, d\,S = N\,(H, H_0)\,(\mu - \mu_0)\, d\,S$$

where the subscript zero refers to the surrounding medium. But the Maxwellian elemental effort being given (outside of the factor $1/8\pi$) by the value of the quantity P_0 under the integral sign in equation (25), in air, it is clear that the quantities to be integrated in (25) and (26) cannot both give the true elemental effort. It is commonly admitted that the quantity under the integral sign in (26) corresponds to the true effort, so that the Maxwellian effort P_0, considered as an elemental effort, appears

7. In formula (10') of my paper, the last term should be

$$-\frac{1}{m_n^2}\left(\frac{\cos\gamma_1}{\lambda_1} + \frac{\cos\gamma_2}{\lambda_2}\right) \text{ instead of }$$

$$-\frac{1}{m^2}\left(\frac{\lambda_1}{\cos\gamma_1} + \frac{\lambda_2}{\cos\gamma_2}\right)$$

to be fictitious. and it leads merely to the same resultant effort as (26).

For the condition μ = constant, formula (26) becomes, in effect,

$$8\pi F = \int_s (P_0 - P)\,d\,S \qquad (26')$$

But, by virtue of theorem (13), when integrating along the *inside* contour (the iron side) of the *closed* surface S, (since grad μ then vanishes) we have,

$$\int_s P\,d\,S = 0,$$

and we thus see that (26′) actually becomes identical with (25) for any closed surface.

If we consider $-\dfrac{1}{8\pi}H^2$ grad μ as the true effort per unit of volume, we can then scarcely attribute any real meaning to the Maxwellian stresses except in so far as they can be applied in the case of a surface of integration that is entirely closed.

The same remarks apply to the efforts deduced from the variation in the reluctance, which do not prevent us, of course, from assembling the efforts represented by tubes when these are considered component parts of the total effort.

STARTING CHARACTERISTICS AND CONTROL OF POLYPHASE SQUIRREL-CAGE INDUCTION MOTORS[1]

(NORMAN)

NEW YORK, N. Y., FEBRUARY 10, 1926

B. F. Bailey: I should like to point out the use of the following formula

$$\eta = \frac{0.142 \times \text{Lb-Ft.} \times \text{Sync. Speed}}{\text{Volt-Amperes}}$$

in which η is the volt-ampere torque efficiency. By substituting the input to the motor in watts for the volt-ampere input we have the watt-torque efficiency. This formula is of course correct for any speed of the motor, although it is most useful in computing the starting efficiency.

In the case of a squirrel-cage induction motor the starting efficiency will usually be about 20 per cent. The wound-rotor induction motor will show higher values and a high-resistance; squirrel-cage motor still higher values. Split-phase induction motors have starting efficiencies of about 10 per cent.

This formula gives us a ready means of comparing the starting performance of different types of motors.

It can readily be shown that the starting torque of a polyphase motor expressed in synchronous watts is equal to the input to the rotor, but the demonstration is based upon the supposition that we have a rotating field which does not change shape as it rotates. In practise, the field does change its shape somewhat and in fact there may be backwardly rotating components of the field which directly subtract from the torque. In addition, there is some loss of torque due to bearing friction. The result is that the torque as measured by a brake is always somewhat less than the torque as computed from the input to the rotor. My experience has been that usually the actual torque will be from 85 to 90 per cent of the theoretical torque, although instances are common where somewhat higher or lower torques are developed.

K. L. Hansen (communicated after adjournment): Aside from containing useful suggestions and formulas, Mr. Norman's paper assists materially in advancing problems pertaining to the transient phenomena of acceleration and retardation from the rough approximation stage on to a sounder, mathematical foundation.

1. A. I. E. E. JOURNAL, February, 1926, p. 153.

Under the assumption of negligible resistance load, the author has found the secondary copper loss, when accelerating from slip s to slip S, to be

$$\text{Watt-seconds} = 0.00744\ (M\ I)\ N^2\ (s^2 - S^2)$$

And the primary copper loss to be the secondary loss multiplied by $\dfrac{r_1}{r_2}$.

In the October 18th, 1924 issue of the *Electrical World*, I published the following formula for the secondary copper loss: (on account of lack of space, derivation of formulas was not shown)

$$W_s = \frac{W\,G^2\,N^2\,(s^2 - S^2)}{4324} = 0.000231\ W\,G^2\,N^2\,(s^2 - S^2)$$

where the moment of inertia $W\,G^2$ is expressed in lb-ft. changing to poundal-ft. by introducing gravity acceleration 32.2, it becomes

$$W_s = 0.00744\ (M\ I)\ N^2\ (s^2 - S^2)$$

which is identical with the one in the paper. An interesting point in this connection which Mr. Norman does not seem to mention in his paper is that, when accelerating from standstill the secondary; loss is equal to the energy stored in revolving parts.

In discussing motors in intermittent service, I made the following statement in my article:

"Comparing (3) with (1), it will be seen that when a motor accelerates from standstill to synchronism, the secondary energy loss is equal to the stored energy and the primary loss is the stored energy multiplied by $\dfrac{r_0}{r_1}$. As the secondary loss is independent of, and the primary loss inversely proportional to the secondary resistance, it follows that the ratio of secondary to primary resistance should be as high as the rate of acceleration permits in order to reduce the energy loss of the system to a minimum."

It will be noticed that this paragraph covers substantially the discussion on the second and part of the third page in the paper.

It might also be of interest to know that I have used the author's speed-time formula and found it satisfactory in applications where the resistance load is small and the inertia load is high, as, for example, in centrifugal extractors. When there is an appreciable resistance load in addition to the inertia load, however, other formulas give better results.

P. L. Alger (communicated after adjournment): Mr. Norman has given us a complete synopsis of the starting behavior of an induction motor. As he points out, the object of studying starting conditions is to design the motor and the control so as to secure minimum losses at starting and a reasonable, but not excessive, factor of safety in design.

To bring out some of Mr. Norman's ideas more emphatically, there are two points which seem to be worthy of mention. Both of these points arise from the fact that a motor designed primarily for starting duty should have different characteristics from one designed for steady operation. In order to obtain the best starting torque per ampere, it is necessary to have a high rotor resistance, and, in order to obtain low starting losses, it is necessary to have a low primary resistance. These two things naturally result in the designer's making a starting motor with few primary turns and therefore with a very high magnetizing current.

A high magnetizing current results in an appreciable difference between the primary and secondary currents during the starting period. Though Mr. Norman suggests that this difference can be neglected, it is often quite appreciable. As Professor Bailey stated in his discussion of the paper, the torque efficiency, defined as the ratio of the starting torque as measured with a

brake to that as calculated from the copper loss due to the measured primary current and the measured secondary resistance, is usually appreciably below unity. If the secondary resistance used in calculating the torque is the apparent value obtained by dividing the primary input at standstill, less the primary copper loss, by the square of the primary current, the torque efficiency is 100 per cent. But if the true value of secondary resistance is used, the calculated value of torque will be too high, due to the secondary current being smaller than the primary current.

Thus, in the attempt to make a motor with good starting characteristics, the magnetizing current is exaggerated, and so the accuracy of the simple theory which neglects magnetizing current may be said to be less, the better the motor is for starting duty. Mr. Norman, also points out that the existence of eddy currents in the rotor during starting again makes the theory less accurate and generally requires some approximations to be employed in calculating the primary copper loss. These eddy currents are exaggerated, in the attempt to obtain high starting resistance and low starting current without too seriously impairing the running efficiency by the increasing employment of the double squirrel-cage type of winding. However, if a double squirrel cage is so designed as to obtain the maximum possible starting resistance with a given running reactance, expressions for the secondary resistance referred to primary of the form

$$\frac{R}{S} + \frac{S\,X_0}{1 + S^2},$$ and for the secondary reactance of the form

$$X + \frac{X_0}{1 + S^2},$$ may be employed in place of the simpler ones,

$\frac{R}{S}$ and X, and, with their aid, accurate formulas similar to Mr. Norman's may be derived for the time of starting and other characteristics.

H. M. Norman: In answer to Prof. Bailey's remarks concerning what he calls efficiency of the starting torque, I should say that there is nearly always a discrepancy between the measured starting torque by brake and that indicated by the watts loss in the rotor at start. The brake value is sometimes lower and sometimes higher than that given by the secondary loss. However, the average value obtained from a large number of different motors showed that there is only about a four per cent difference.

It should also be remembered that there is difficulty in measuring the input watts correctly, and also in estimating the proper value of the primary resistance (variation due to temperature) to use for calculation of the watts in the primary so as to obtain the correct watts loss in the rotor. In view of these difficulties, the best guide is the average of a large number of motors.

I think this is a very important point because it touches on the accuracy of the loss formulas in the paper. If it were true that this starting efficiency were appreciably below 100 per cent then the starting losses would be greater than the formulas in the paper indicate.

If there is no unbalance of phases, however, then it is my opinion that any adjustment of the constant 0.00744 in the loss equations need not exceed the addition of the four per cent already mentioned.

In reply to Mr. K. L. Hansen's remarks, I think it unfortunate that the same formula should have to be worked out independently at two different times, but in this case it has the comforting feature that we are both in exact agreement.

Regarding the fact that when starting from rest and accelerating to synchronous speed the secondary loss is equal to the stored energy of the system (this includes the energy of all the moving parts). I should like to point out that I purposely avoided mentioning this fact as it is subject to misuse for the following reason. Suppose that for a given system on account of the nature of the application the rotor of the motor has high resistance so that the full-load speed is say 90 per cent of synchronous speed. Then if the secondary loss be taken as equal to the stored energy of the system, it would be found to be 81 per cent of what it would have been had the system been accelerated to synchronous speed. This is not true, however, as the loss in the rotor under these conditions is equal to 99 per cent of this value.

This error is approximately equal to twice the full-load slip and even for low-resistance rotor motors is not altogether negligible.

Fig. 1 herewith gives a diagrammatic representation of the proportions of loss in the rotor of the motor and the stored energy of the moving parts. Consider a motor that has been accelerated from rest and has reached a speed proportional to $F\,C$ on this diagram where $F\,A$ represents synchronous speed. The area $F\,C\,D$ bears the same ratio to the stored energy of all the moving parts as the area $D\,E\,G\,F$ bears to the loss in the rotor. These areas become equal if the motor starts from rest and accelerates to synchronism so that for this particular case (*and this particular case only*) the loss in the rotor equals the stored energy of the moving parts.

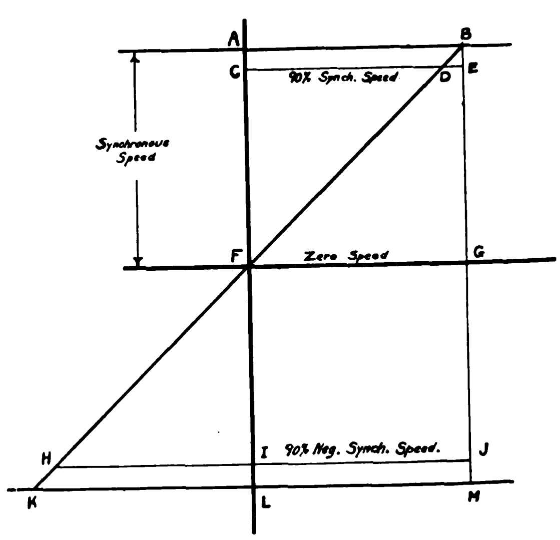

Fig. 1

This diagram also shows the ratio of lost and stored energy to the loss in the rotor when the rotor is plugged by extending the diagram into the negative-speed region. If a motor is running at say 90 per cent of synchronous speed and is plugged, the rotor reversing to 90 per cent synchronous speed in the reverse direction then, (referring to Fig. 1,) the energy lost in the moving parts by bringing them to rest is represented by area $H\,F\,I$, the energy gained by bringing the moving parts up to 90 per cent synchronous speed is represented by area $C\,D\,F$, and the energy lost in the rotor by area $D\,E\,J\,H$.

Referring to Mr. Hanson's statement that the short paragraph in his article covers substantially the discussion in part of my paper, I should point out that on the second page immediately following the loss formulas, I made a statement of approximately the same length and more or less equivalent to that in Mr. Hansen's article, and as I did not repeat myself in the subsequent paragraphs, I cannot see that his claim is well founded. Further, where there are only a few cycles of operation per minute I do not agree with Mr. Hansen's statement that the secondary resistance should be as high as the rate of acceleration will permit in order to reduce the energy loss to a minimum. This is neglecting entirely the losses during the running period. There are so many different cycles of operation that it is not desirable to

compile an abundance of formulas to give the best value of secondary resistance for each, but as there is one cycle which is perhaps the most common, I might add the following formula:

$$r_2 = \sqrt{\frac{0.00744\,(M\,I)\,N^2\,(1 - S^2)\,r_1}{\phi\,I_2^2\,t\,K}}$$

(For inertia starting loads only)

Where

I_2 = Secondary load current.

r_2 = Value of secondary resistance which gives the minimum losses over an entire cycle consisting of a start from rest to speed of $N\,(1 - S)$ and a full-load run for a time $= t$ (seconds) and a shut-down of any length of time. The constant is the ratio of effective resistance at start to that at full load and is slightly greater than unity.

The value of r_2 as obtained from this formula is for the load condition, $K\,r_2$ being the effective resistance at start.

Mr. Hansen seems to understand that I say that my speed-time formulas applied to all types of loading conditions. However, the method by which they were evolved, combined with the paragraph on the last page of my article drawing attention to friction or hauling loads, shows this impression to be incorrect.

In reply to Mr. Alger's statements, I should like to point out that the object of making the secondary resistance high for motors which are used for frequent starting is two-fold. It not only reduces the starting current, but also reduces the total losses during acceleration. The reduction of the primary resistance by means of reducing the primary turns has little or no affect on the starting losses, however, when measured in joules, and motors intended for frequent starting may sometimes be designed by changing the secondary winding only.

Motors to be used for special starting duty can be built with either a high rotor resistance, few primary turns to strengthen the field, or a combination of both, depending on the nature of the application.

If the starts are very frequent then the first method gives the best results as the starting losses are lowered and this results in a lowering of the total losses over a complete cycle of operation provided the rotor resistance is not increased excessively.

If the number of starts are very few and high starting torque is required on account of, say, excessive static friction, then the second method can be used provided the increased starting current is permitted and that low power factor is not of any great consequence.

When there are limits placed on the starting torque and current and the full-load power factor and efficiency, then the combination of more rotor resistance and fewer primary turns is used to meet these requirements. Again it may be used when the application requires high starting torque and a medium number of starts and stops.

From this it can be seen that the designer does not always use few primary turns.

Regarding Mr. Alger's statement that the use of few primary turns exaggerates the magnetizing current and so upsets the simple theory that during acceleration the primary and secondary current can be considered of equal value, I cannot agree. Neglecting saturation, the magnetizing current changes inversely as the turns squared. The starting current also changes in the same ratio. Therefore, the ratio of these currents is the same no matter what the primary turns may be. Should saturation be taken into account, then the consequent increase in current applies much more to the starting current than to the magnetizing current during acceleration because at start the main field is only one-half or one-third of its value at synchronous speed, while the leakage paths are saturated.

The difference between the primary and secondary current of the motor of average size and speed is about three per cent so that the value of the secondary resistance as given by formula (1) in the paper is about six per cent too small. Since the secondary loss (measured in joules) during acceleration is independent of the secondary resistance, then this error does not effect the rotor loss.

Now consider the primary loss during acceleration: the exact value could be obtained by multiplying the secondary loss in watts by the ratio of the primary resistance to the true value of secondary resistance and then by the mean square of the ratio of primary to secondary current over the starting period.

It so happens that this ratio of the mean square over the entire starting period is very nearly equal to the ratio of the square of the primary to secondary current at the instant of starting which is also the ratio of the true value of secondary resistance to the value obtained by using formula (1) in the paper. Therefore, by using formula (1) to get the secondary resistance and assuming the primary and secondary currents equal, very little error is introduced.

To illustrate how negligible this error is, consider a 50-h. p., 6-pole, 60-cycle motor. The ratio of the mean squares of the primary and secondary currents up to 90 per cent synchronous speed is equal to 1.041. The ratio of the true value of secondary resistance to that calculated by formula (1) is equal to 1.031, so

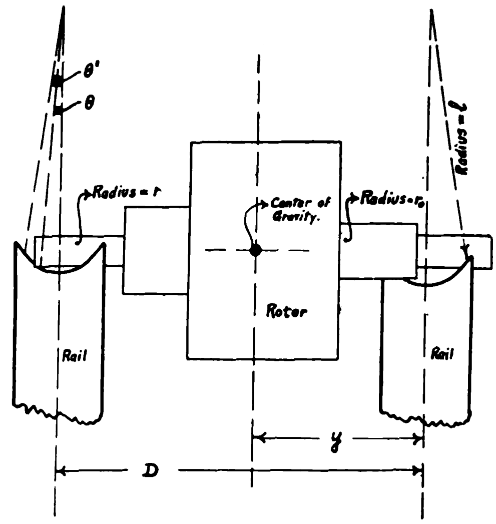

Fig. 2

that there is only one per cent error in calculating the primary loss. Consider an extreme case of a 50-h. p., 20-pole, 60-cycle motor with only 4¾ times starting current and 68 per cent full-load power factor. The ratio of the mean currents to 90 per cent synchronous speed is equal to 11.37 and the ratio of true to calculated secondary resistances is equal to 11.17 which shows that there is less than two per cent error even in this extreme case. From this it is obvious that it is sufficiently accurate to use the method given in the paper.

Mr. Alger seems to be under the impression that the work on reversing motors, in which I made correction for eddy-currents in the rotor, had something to do with a difference in the primary and secondary currents. This is not so; the reason for finding the primary loss by the method worked out in the paper was on account of a varying ratio between primary and secondary resistance while retarding the speed.

Regarding the statement that similar formulas to those given in my paper could be worked out for double-cage windings, I think that these formulas would be very complicated and therefore would not be extensively used. Further, it is doubtful if

such a motor would have any advantages over a high-resistance rotor motor as the higher full-load efficiency is misleading, the true guide being the total losses over a complete cycle of operation. Also there would have to be a decided advantage in favor of a double-cage winding to warrant its use as it is more complicated and expensive.

I should like to add the following formula which gives the radius of gyration for rotors which have journals with bearings of different diameter on each end. This measurment can be made by using the circular rails illustrated in Fig. 7. Squirrel-cage motors have usually the same diameter of bearing on each end but it is sometimes necessary to know the radius of gyration of other rotors. This can be done with the same equipment. Referring to Fig. 2 herewith

let

v = vel. of center of gravity of rotor.

R = radius of gyration radially (feet).

R_1 = radius of gyration about axis perpendicular to the shaft and through the center of gravity.

ω and ω_1 are the respective angular velocities.

Then gain in kinetic energy

$$= \frac{1}{2} M v^2 + \frac{1}{2} M R^2 \omega^2 + \frac{1}{2} M R_1^2 \omega_1^2$$

Loss in potential energy

$$= M g (\theta'^2 - \theta^2) \left[\frac{1}{2} \left(\frac{r_0}{r} \right)^2 (l - r_0) \left(1 - \frac{y}{D} \right) + \frac{1}{2} (l - r) \frac{y}{D} \right]$$

Substituting $\omega_1 = \omega \dfrac{r_0 - r}{D}$

$$\omega = \frac{l}{r} \frac{d\theta}{dt}$$

$$v = \left(\frac{D - y}{D} r_0 + \frac{y}{D} r \right)^{\omega}$$

Equating these two quantities and integrating gives:

$$R = \sqrt{\left(\frac{P}{2\pi l}\right)^2 g \left[r_0^2 (l - r_0) \left(1 - \frac{y}{D} \right) + r^2 (l - r) \frac{y}{D} \right] - \left[r_0 \left(1 - \frac{y}{D} \right) + r \frac{y}{D} \right]^2 - \left[R_1 \frac{r_0 - r}{D} \right]^2}$$

The term $\left[R_1 \dfrac{r_0 - r}{D} \right]^2$ can be neglected.

From this equation it can be seen that the short-cut method which suggests itself of taking the average of r and r_0 and then substituting in the formula given on the tenth page of my paper does not give sufficiently accurate results.

Discussion at Madison Convention

TESTS OF PAPER-INSULATED HIGH-TENSION CABLE[1]

(FARMER)

MADISON, WISCONSIN, MAY 7, 1926

W. S. Clark: In connection with the figures given in Mr. Farmer's paper, one should not lose sight of the fact that there is no insulation of which we know in which the strength increases in direct proportion to the increased thickness of insulation.

The company by which I am employed makes small static condensers or capacitors for power-factor correction. These are operated with a stress of about 300 volts per mil, the total thickness of insulation being about 4 mils. We have found that if we desire to increase the voltage from 1200 to 2400 volts on these condensers, to secure the same factor of safety and freedom from breakdown it is necessary to more than double the thickness of the insulation.

In a general way the strength of saturated paper insulation, assuming uniform quality, appears to increase only about as the 0.8 power of the thickness and not directly as the first power.

With reference to the test referred to in Mr. Farmer's paper, regarding formation of wax or X compound in oil, the test as at present specified apparently cannot be duplicated in different laboratories with the same material. When the test is brought to a condition in detail where it can be duplicated in different laboratories with the same results, then I think it will be good.

E. C. Willman: We noticed that the X compound was greatest at the surface and in the layers of paper nearest the conductor; that is, at the point of highest stress. We therefore attempted to form the compound by stressing petrolatum placed between variously shaped electrodes, but without success. With the thought in mind that occluded air might be responsible for the formation, we tried bubbling ozone through melted petrolatum. This did not produce any X.

Later we dissected a piece of badly wrinkled cable which had a deposit of X in the wrinkles in the lead,—the point of least stress,—and had only traces at the conductor. This led us to believe that the formation was due to electric stress in combination with rarified atmosphere. We then made up a Geissler tube of glass 8 in. long and ¾ in. in diameter. An electrode was sealed into one end and the other end was provided with a rubber stopper through which an electrode and a smaller glass tube were inserted. Some petrolatum was placed in the tube, which was then exhausted to 28 in. of mercury and potential from a one-in. spark coil was applied to the terminals of the tube. In a short time the peculiar granular structure of the X compound became apparent on the surface of the petrolatum. Its identity was established by chemical and microscopic tests.

D. M. Simons: To my mind, the outstanding point of this paper is Fig. 7. If the breakdown strength of three-conductor cables under long-time application of voltage is only half that of single-conductor cables, or even if it is considerably less than single-conductors while not being as low as this figure suggests, then this is a fact of outstanding importance in the cable industry. I am interested in it not only for its general bearing, but also because it is a point that the engineers of the company with which I am associated have been claiming for many years, especially in connection with the use of three-conductor Type H cable in place of the usual belted construction for the higher voltages, say, 22,000 volts and higher. This form of cable is of course equivalent in its electric field to three single-conductor cables under one lead sheath, and our claim has been that this form of cable would avoid many of the troubles that have been observed in the outer layers of conductor insulation and especially in the filler spaces of the usual form of three-conductor cable and joints when used in the upper range of voltage. It is very significant to have this effect confirmed in such a striking manner by Mr. Farmer.

Percy Dunsheath: Mr. Farmer referred to the relative importance of the cable and the other part of the installation. The cable is, after all, from a financial point of view, *the* part of an installation to watch for possible improvement with a view to cutting down the costs of development work.

One point I should like to make is that the first thing to do is to settle this question of acceptance tests. If we can arrive at a

1. A. I. E. E. JOURNAL, May, 1926, p. 454.

test that will prove quality, then I think quality will follow. If there has been any delay in improving quality, it has been because we have not known what we wanted and have not been able to recognize quality when it already existed. We are still using the standard pressure test in spite of the fact that after a cable has been pressure-tested in a factory, if it isn't a good length of cable, the pressure test may leave it on the point of breakdown and it is sent out of the factory in this condition.

Unfortunately, after the completion of these three papers we are not left with a clause which we can put into a specification,—an acceptance clause; but I think we are all agreed that the work, particularly Mr. Farmer's analysis of the time–voltage curve, does bring us very much nearer arriving at a clause of this kind. I don't know whether it has been done before (to me it is quite new) but I see that Mr. Farmer has analyzed the time–voltage curve into a number of component time–voltage curves, some for the bad parts of the cable and some for the good. I think that that is a very important observation to make because if a cable consists of a number of different parts, some with a low time-voltage curve and some with a high time–voltage curve, then a short-time, high-pressure test is a means of finding out weakness in the cable. If there is only one time–voltage curve for the whole cable, then a short-time high-pressure test can be carried out but it may be destructive.

Page 8 of Mr. Farmer's paper advocates adopting a standard load. Generally speaking I think that that is a good thing. If we could have a standard load which we could put onto any method of measuring losses,—dynamometer, bridge, or any other means,—and so arrive at a distinct, definite calibration, it would be a considerable step forward. I should suggest, however, that instead of the type of load which he proposes and which has to be measured, itself, we adopt a load which can be built up to a known power factor. I should suggest a condenser with negligible loss combined with a definite pure resistance.

On the eleventh page of Mr. Farmer's paper, those curves showing the variation of rising power factor with time are important and interesting and I am wondering whether the rise which he sometimes gets and sometimes does not get is due to a very slow increase of hydrostatic pressure. If so, possibly we can follow out that line with a view to getting an acceptance test, a cable which didn't give that original rise being a better quality than one which did.

Mr. Farmer describes the end which he uses for a three-conductor cable. I should just like to set forth a suggestion which I found useful in taking off ends for that type of test. To avoid the cost of a wiped joint, I have used ebonite cones about ½ in. thick, with a taped joint. Over the thickened dielectric on each core, I have carried tin-foil clear up to the crotch, with the result that no breakdowns can take place in the crotch. It is quite easy to bring an end of this kind to the highest voltage required.

I agree that the preparation of these samples is important. It is really astonishing the differences one can get on time—voltage tests on the same make of cable by first inverting the cable and putting the ends in oil, then turning the ends upward and putting on oil pockets. If anything should be standardized, it should be the method of making the ends. If an end is made which prevents the escape of any gases generated, up goes the time–voltage curve.

R. J. Wiseman: Referring to Fig. 1 of the paper, we find existing a rather interesting property aside from the wide variation in insulation resistance. The variation is very much greater for the compounds giving high values of insulation resistance.

Fig. 4, showing the distribution of failures for five-minute tests bears out what some of us believe; namely, that failure on a reel test is due to mechanical defects and will be detected with a reasonably high voltage. Too few tests are reported for 15 min. to be able to draw any conclusions. It is quite likely that Mr. Farmer is right, that, due to pre-testing by the manufacturer, failures on short time are eliminated before inspection.

Table I shows an improvement in breakdown voltage for each year; but there is still room for improvement. When the maximum dielectric strength at the conductor approximates the dielectric strength of a sample between flat plates we shall have reached the limit.

Figs. 5 to 10 inclusive are of interest in suggesting the limiting stress we can put on a cable indefinitely. At the present time, for methods of manufacture I believe 125 volts per mil is nearer the safety limit of operation than 150 volts per mil. This will give a factor of safety of about four or five on strength of material.

Mr. Farmer's suggestion of a standard load for checking dielectric-loss testing equipment is a very good one; besides the load he describes, I should like to advise his considering a load giving larger charging currents and higher power factors. I have found this important in making check tests on equipment.

A study of the change in power factor with time for different stress values is one of the best means to determine the aging quality of a cable. We would expect a slight increase in power factor for about 50 hours and then either constant or decreasing values.

I hope Mr. Farmer will be able to solve for us the proper manner of preparing samples of cable for high-voltage test. At present we do not get the real short-time breakdown voltage due to flashovers. Potheads are of great help but still not sufficient. The time consumed in preparing ends for test is enormous. Any means of reducing it and still permitting of higher voltages is welcome.

I should suggest that Mr. Farmer replot Fig. 30, using the maximum voltage stress at the conductor. Even though he may not think it accurate, he will get a better comparison of the test on cables and condensers for wax formation.

W. A. Del Mar: Unfortunately, the test for X which is described in Mr. Farmer's paper is open to the serious objection of giving discordant results. A case which came up quite recently was in relation to a barrel of compound which we had had in our laboratory for some weeks. We took out a sample which we designated A, divided it in two, sent half to the Electrical Testing Laboratories and kept the remainder ourselves. The Electrical Testing Laboratories sent back a report, "Abundant wax formation." Our laboratory, using apparatus as described in Mr. Farmer's paper, reported "none"; so we thought we would make a check test. We took another sample B out of the same barrel, again divided it in two, sending one part to the Electrical Testing Laboratories and keeping the remainder ourselves. They reported no wax and our laboratory reported considerable wax.

That bears out the general condition we have in our own laboratory; *i. e.*, we cannot obtain consistent results. We get X in a given compound perhaps in three or four tests in succession, and then, for some unknown reason, without any apparent change, the opposite result is obtained.

Even if the test can be perfected so as to be susceptible of unfailing check, insufficient evidence has been offered to connect the test with operating results.

Another interesting feature of Mr. Farmer's paper is the apparently greater dielectric strength of insulation on single-conductor cables as compared with triplex cables, as shown in his Fig. 7. This diagram, however, shows maximum stresses, as computed from the ordinary logarithmic formula. Recent researches by P. L. Hoover[2] have shown that the maximum stresses at failure cannot be derived from that formula, and that average stresses are a better criterion. As the average stress in a single-conductor cable is a much smaller fraction of the con-

2. *The Mechanism of Breakdown of Dielectrics*, by P. L. Hoover, A. I. E. E. JOURNAL, September 1926, p. 824.

ventional maximum than in a triplex cable, the discrepancy which is made to appear in Fig. 7 disappears.

F. A. Brownell: For testing purposes Mr. Farmer has pointed out the need of an end bell that could be constructed or connected in a minimum of time. This is one of our chief difficulties at the factories today and it seems that more time and thought should be given to this subject. We have used, with some modification, the end bell shown in Fig. 22 of Mr. Farmer's paper and have had very satisfactory results, the only objection being the time required for wrapping the conductors with varnish cambric. I believe this can be overcome by the use of the roll of tapered paper that the Pirelli Company used in making up the joints on the 45-kv. line of the United Electric Light and Power Company of New York City. This paper could be made up into rolls and placed over each of the three conductors and tightened. This would give a snug-fitting insulation and the crotch would be entirely filled. It may be that the taper of the paper would have to be changed somewhat to give the desired fitting.

F. M. Farmer: First, I desire to make two corrections. In the advance copy printing the note under Fig. 7 refers to Fig. 12. This should refer to Fig. 6. In the captions for Figs. 25, 26 and 27 the word "wax" was used. This is unfortunate, since the product produced is not wax in the sense that the term is used in industry. In fact it is quite different from any known substance familiar to oil technologists and has none of the characteristics of any variety of wax. Furthermore, it is not soluble in any of the ordinary solvents. Mr. Del Mar has suggested the expression X. In view of our lack of knowledge of this substance, this designation seems particularly appropriate.

From the tests which he describes, Mr. Willman implies that this deterioration is due to the action of ultra-violet light resulting from a sufficiently high electric stress across microscopic air voids in the compound. Whether this X formation is due directly to the application of stress or due to the action suggested by Mr. Willman, which, in turn, requires the presence of stress, is, from a practical standpoint, immaterial to the user. He is interested in knowing whether or not the compound in the cable remains stable under the conditions of use which involve only two variables, namely, stress and temperature.

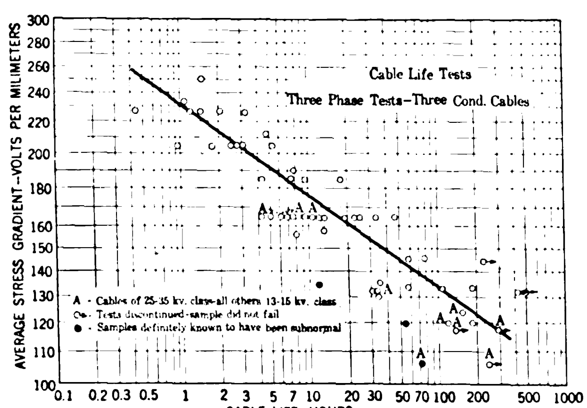

Fig. 6a—Cable Life Three-Phase Tests—Three-Conductor Cables

Mr. Del Mar has indicated that the test proposed for X formation is not dependable. It is probably true that it is not very sensitive where the compound forms X with difficulty so that X is formed at one time and not at another. Just why this variation occurs we do not know as yet but it is believed that the test being so simply and easily made justifies its use as a rough indicator of the probable performance of the compound.

Mr. Del Mar also raises the point that it has not been definitely demonstrated that this kind of deterioration in compound in a cable necessarily results in ultimate failure. This is true, but while we haven't positive proof that X in cable is objectionable, there is altogether too much circumstantial evidence available to justify engineers assuming that X is *not* objectionable. Since compounds can apparently be developed which do not form X and which are otherwise satisfactory, it seems only good engineering to avoid the use of X-forming compounds, even though we are not positive that they are objectionable.

Referring to Figs. 6 and 7, some additional data have been obtained since these diagrams were made and new diagrams are given herewith,—Fig. 6a corresponding to Fig. 6 and Fig. 7a

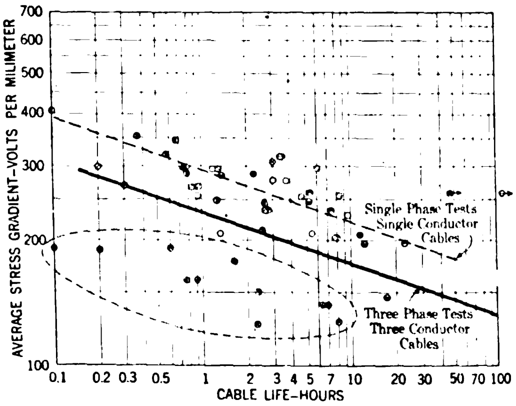

Fig. 7a—Cable Life Tests—Single-Conductor Cable

corresponding to Fig. 7. It will be observed that the slope is the same so that we are quite convinced that the seventh-power relation is approximately correct for at least the types of cable involved in these tests. Of course, if there is a pronounced change in the method of construction or in the kind of compound used in high-tension cables, the slope of these curves will undoubtedly be affected.

The point mentioned by Mr. Simons,—namely, the apparent superior showing of single-conductor cable over three-conductor cable,—is obviously of great importance; so much so, in fact, that a rather elaborate systematic investigation is being planned with specially constructed cable to determine the correctness or otherwise of this indication. Mr. Del Mar points out that if average stress instead of maximum stress had been used in preparing these diagrams, the apparent difference between single-conductor and three-conductor cables would have been less. This, of course, is quite correct. For instance, the average *maximum*-stress gradient to give a life of 10 hr. in three-conductor cable is 215 volts per mil and in single-conductor cable, 400 volts per mil, or an apparent increase of 86 per cent. The average *average*-stress gradient to give a life of 10 hr. is 175 volts per mil in three-conductor cable and 220 volts per mil in single-conductor cable or an apparent increase of 26 per cent. But which of these two bases is the true measure of dielectric strength of the cable as a whole? As we all know, there has been much discussion of this point and papers have been presented before this Institute giving evidence which apparently favors both of these gradients as well as intermediate ones. Eventually we shall have the true answer; and while it is highly probable that it will not be the maximum-stress gradient, it is also probable that it will be something higher than the average gradient. It seems reasonable to conclude, therefore, from the evidence presented here, that the inherent dielectric strength of single-conductor cable is on the average substantially higher than that of three-conductor cable and that the difference may be of the order of 40 or 50 per cent. However, as previously stated, this apparently large difference must be confirmed by further investigation before a final conclusion is justified.

Referring to Capt. Dunsheath's suggestion in connection with the proposed standard load for dielectric loss testing that various power factors be obtained by the use of series resistance, I should say that we have had this point in mind.

THE EFFECT OF INTERNAL VACUA[1]

(Del Mar)

Madison, Wisconsin, May 7, 1926

Wallace S. Clark: In connection with Mr. Del Mar's paper it should be remembered that the Pirelli idea is to keep in the cable, at all times, a pressure in excess of atmospheric pressure.

Percy Dunsheath: I think Mr. Del Mar has gone a little bit too far although probably not intentionally. I am rather afraid the impression that his conclusions will give is that all cables for high voltages should be supplied with oil ducts. I don't think he intended that and certainly I should resent any such suggestion, because I am sure that our experience with 33,000-volt cables, unhappy as it was years ago, today proves definitely and quite conclusively that a 33,000-volt cable can be made to give satisfactory service without oil ducts, whatever conditions of high voltages are called for.

R. J. Wiseman: Mr. Del Mar has presented to the public the views some of us have had for some time as to the effect of voids in cables. However, I think it would have been better if he had eliminated reference to atmospheric pressure. Voids are created in a cable due to the oil contracting as it cools and endeavoring at the same time to maintain a balanced pressure. This means that if a cable is sealed and the oil cools, it is below atmospheric pressure. A cable in operation with sealed ends is rarely at atmospheric pressure, usually above, and below only when cooled.

The size of voids in a cable will depend a great deal upon the type of oil and the freedom of motion. The size of the voids increases as we lower the temperature. This results from the capillary attraction of the oil to the paper. A tacky oil holds best and is likely to produce small voids rather than large ones, the latter being more objectionable.

Fortunately, shortly after a cable is installed at 0 deg. cent., it assumes the temperature of the ground and therefore heats up, eliminating most of the voids produced at low temperature. It is most desirable to load a cable up for a few days after installing it in order that the oil may become stabilized locally before making any voltage tests. Here the purchaser could help very well by actually putting a cable into service for a week and then making the acceptance test. This should be done on all high-voltage cables.

Take the case of the cables when they cool down after the load is removed, but the voltage is still on. Here it is advantageous that the dielectric loss be sufficient to heat the cable a few degrees, thus preventing the formation of voids. This brings out an important point. A reasonably low dielectric loss at low temperatures is preferable to a very low loss.

Creation of voids in joints is most probably due to the draining of the oil into the cable. It is not a case of stabilizing pressure, but rather improvement in cable impregnation. In such a case, the heating of the cable with load does not help the joint. The joint is on the way to failure unless refilled.

Herman Halperin: The impression is given in the paper that transient voltages cause many cable failures. In meetings of the A. E. I. C. Subcommittee on High-Voltage Transients on Underground Cable Systems, no information was given to show that transients cause any deterioration of the insulation. As expressed at a meeting of the subcommittee a few weeks ago, the opinion seems to be that the transients cause failures at unusually weak spots in the insulation; that is, the cable has usually been found obviously deficient at the point of failure, which cannot be said about cable failures in general.

1. A. I. E. E. Journal, July, 1926, p. 627.

The failures due to transients have generally been distributed over all parts of the underground systems, and rarely have they been located at any particular point, as may be inferred from the paper. This experience has been reported by several companies and is checked by the experience of the Commonwealth Edison Company.

In recent klydonograph investigations of surges on eight large systems, it was found that 85 per cent of the surges were less than twice normal voltage. About 1 per cent of the surges exceeded four times normal voltage, and it appears that surges must reach this magnitude to be disturbing. The latter surges may be slightly in excess of the full-reel test voltage at the factory. On the other hand, samples of high-tension cable will usually withstand test voltages of 7 to 12 times rated voltage of the cable for about one minute. The duration of the transient voltage is only a fraction of a second and Peck and others have presented data to show that the dielectric strength of insulation increases very rapidly as the time is reduced to a fraction of a second. One manufacturer has reported a case where the insulation withstood transient voltages of about three times the breakdown voltage he had been obtaining on dielectric-strength tests on samples. In regard to the decrease in dielectric strength on account of the higher frequency of the surges, it appears that this is more than counterbalanced by the increase in dielectric strength due to the shortness of the application of the transient.

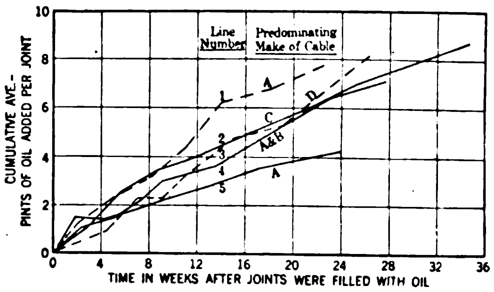

Fig. 1—Curve Showing Addition of Oil to 22-Kv. and 33-Kv., Three-Conductor Oil-Filled Joints With Insulation Formed

In general, with cable of high quality, such as indicated as being desirable in the paper on the Quality Rating of High Tension Cable by Mr. Roper and myself, evidence seems to show definitely that transients will cause no failures or have any deleterious effects on the insulation.

In regard to the point in the first paragraph of the paper, that sections upon removal from ducts will withstand severe high-voltage tests even though they have failed in service, the failure occurred at the spot of lowest quality. These weak and irregular spots have been found repeatedly in accelerated life tests in Chicago, and the experience has been that if a portion a few feet long were removed from a section of cable, the voltage rating of the section would then be increased from 15 per cent to over 100 per cent. In the last part of the paper, there are listed the essential characteristics for successful high-tension cable, but the item of uniformity is omitted, although experience shows that it is of paramount importance.

In connection with expansion and contraction incidental to the operation of cables and the consequent formation of voids, the Commonwealth Edison Company has had an interesting experience with oil-filled joints on several lines of 22- and 33-kv., three-conductor, impregnated paper-insulated cables with fair impregnation. The joints were filled with a switch oil having a viscosity of about 200 seconds (Saybolt) at 25 deg. cent. Periodically the joints were checked as to the level of the oil in them, and sufficient oil was added (or removed in a few cases) to restore the level to its normal plane. Fig. 1 herewith shows

the cumulative average number of pints of oil per joint added to these joints during the period of 5 to 8 months. In the average case, a total of about one gallon has been added in six months to each joint. This means that each length of cable had sufficient void space for one gallon of compound, which is sufficient compound to impregnate completely about 9 ft. of cable.

F. A. Brownell: Apparently Mr. Delmar's paper explains why so many of our cable failures occur during the off-peak when the cable is cooling or cool.

In 1923 we had 107 failures in our 13-kv. cables. Sixty-one of them could not be classified as to cause. Forty-two of this group failed during the early morning hours while the cables were carrying practically no load. Other years have shown similar results. If it is possible for vacua to form in our present cables at a temperature they would attain on an off-peak load, it would seem that this condition could be overcome by a rapid equalization of oil under pressure, the use of a less viscous oil than is used at present, and the installation of a reservoir on joints filled with the same oil that is used for impregnating the cables.

We have found the formation of X in cables operating at 26 kv., while in the laboratory it has required a potential of 100 kv., on the same make and type of cable before formation occurred. In cables impregnated with a rosin-content compound we were unable to produce it at potentials up to 210 kv. We have had cables that have failed in service operating at 26 kv. and have shown signs of ionization. This would indicate that the pressure in the cable must have been below atmospheric to have had ionization at this voltage.

D. W. Roper: Mr. Del Mar's theory seems to be borne out in a number of instances in our experience. He refers to the contraction of the compound in the cable; we have had a similar experience with compound in the joints. In some of our 33-kv. joints, we use a compound similar to that used in the cable; that is, a petrolatum. This particular line was operated practically without load for weeks at a time during the winter months. It was a tie line between generating stations and it was largely a reserve line on the generating capacity in the two stations.

After some weeks of operation during the winter season, we began to notice a bulging of the joints. We tried to discover the cause of this bulging, and as nearly as we could determine, it was due to the formation of small vacua or voids in the compound in the joint. Had this cable been operated every day at a load which would warm the compound up to the melting point, the voids, when they reappeared, would probably not have reappeared at the same location. You can find these voids if you will take a mass of compound, either in a can or a glass vessel, and expose it to low temperature; you will find small voids perceptible to the naked eye, distributed throughout the entire mass of compound. If you take a different kind of a compound which has more cohesion between the particles,—a more viscous compound,—then when the compound cools there will be more of a settling of the horizontal surface so that there will be a serious depression, but with a compound of this kind, there is no great amount of settling of the surface; the cooling occurs by the formation of these minute voids throughout the mass of the compound.

It appears that these small voids will occur now and then adjacent to the conductor insulation which is in the joint, and when these occur, the ionization, due to the discharge in the voids, will occur, and in the course of time these voids will enlarge. By careful examination of the joints when opened, we actually found some voids of approximately the size of the joint of the thumb, and adjacent to such voids, we found the evidences of ionization in the factory-applied insulation in these joints.

There was undoubtedly some pressure within these joints as shown by the bulging of the lead sleeve at the joint, although these lead sleeves were covered with broken cement, so that it not only stretched the lead sheaths but cracked the cement. The trouble has been cured by removing those joints so as to remove this petrolatum and refill with a thin oil. This is the oil referred to by Mr. Halperin in his discussion and diagram. No such trouble occurred when the joints were filled with oil; in fact, trouble could not occur in a thin oil which was so thin as to be fluid at even the minimum operating temperature of the cable. The nature of the compound used in the joint, as nearly as our experience shows, must either be fluid or be of a character which will not permit the formation of these internal voids throughout the mass of the compound.

T. F. Peterson: One must recognize that the burden of failures resulting from conditions characteristic of long jointed lines, must be borne by operating companies. Failure due to vacua in installed cable falls into this class. The following is submitted because it is thought that too much importance has been attached to this condition.

Spaces or air pockets in insulation may be due to:

1. Contraction of oil after impregnation
2. Expansion of lead due to bending
3. Contraction of compound due to cheese formation.

Mr. Del Mar makes no attempt to show the harmful effects of pockets containing gases at atmospheric pressure. Indeed he attaches no importance to these. Failures are considered to be due to the fact that *after* cables are installed, vacua are invariably produced, ionization takes place and ultimately failure results. This reasoning tends to exonerate the manufacture and shift cause of failure to a rather unfortunate condition with which operating companies must cope.

It is my contention that air spaces, even at atmospheric pressure, constitute a very important cause of failure (the action being somewhat slower than for vacua, nevertheless very pronounced) and since, in a large measure, they are due to causes 1 and 3, which are of manufacturers' concern, it follows that the latter must assume some part of the responsibility for failure. To substantiate this claim, consider the following:—Assume an air pocket at atmospheric pressure in a valley between turns of 5-mil paper; breakdown of this film, 0.0127 cm. thick, occurring at 68.3 kv. per cm. If the dielectric constant is assumed to be 3.5 the potential gradient in paper will be $\frac{68.3}{3.5} = 19.5$ kv. per cm. or 49.5 volt per mil. This is not an uncommon value for average gradient under operating conditions and so it appears that harmful results may easily result.

It remains, then, to explain the differences observed by the author between breakdown results on long and short lengths of cable. A partial explanation is given; namely, that of vacua. There is, however, another factor which tends to account for the results in-so-far as it assists the case of the short length. The latter is usually tested under oil where chances for reimpregnation are especially good; hence better test results.

The last paragraph of the paper gives ways of avoiding vacua. In the light of this discussion, it would seem that ways of diminishing possibilities of forming air pockets would have been a more appropriate subject for consideration.

W. F. Davidson (by letter): I am glad to note that Mr. Del Mar has attacked the problem of high-voltage cables from an angle which seems to be more in the direction of a real solution than many of our discussions of the "transient bugaboo." After all is said and done, our cables must be able to withstand such normal and transient voltages as do exist.

There is one phase of the paper which I wish to discuss; namely, the formula for this X or "cheese." When we have once definitely ascertained this factor we shall have made a long stride toward determining the true cause of its formation and definitely stating the effects of internal vacua, etc.

In the first place, I am surprised that it has been found possible to determine a chemical formula for X, because the original oils are known to be highly complex mixtures of several compounds and it is difficult to understand how we may be assured that the

resulting X is really one chemical individual. Until we have this assurance, a chemical formula has no significance. Possibly Mr. Del Mar can give his data.

In the second place, as I understand the processes of analysis used in such cases—assuming that we have proved the existence of a single chemical individual—we would obtain the oxygen ratio by determining what was left after the hydrogen and carbon have been determined. This should give a definite value for n.

Finally, we have no evidence presented to substantiate the statement that "it is apparently highly polymerized." Here it is necessary to assume again that the substance is a chemical, individual for it is usual to ascertain the degree of polymerization by determining the molecular weight; and a mixture of several chemical substances cannot have a single molecular weight. But even so, the determination of molecular weight seems almost impossible in the case of a solid substance which is non-volatile and almost insoluble.

J. A. Duncan (by letter): Mr. Del Mar's formula $(C_{12}H_{28}O)_n$ is of special interest to those of us who have been studying the deterioration of impregnating compounds and it is this formula which I wish to discuss. In order to include all possible interpretations of such a formula, one must discuss all possible values of n. This means all values of n from plus one to plus infinity, since zero or negative values have no meaning.

Let us begin with the case n equal to unity. The formula is then $(C_{12}H_{28}O)$, which is very remarkable, because 26 atoms of hydrogen alone completely satisfy all the available valency bonds in a single molecule of 12 carbon atoms and it is difficult, if not impossible, to imagine how the other two hydrogens and one oxygen are attached to the molecule. The straight chain structure in normal paraffins contains the maximum number of hydrogens possible if we attribute to carbon the valency four which, I believe, has always been found to be its maximum value. It is seen from the diagram of a paraffin (dodecane for example)

$$\begin{array}{cccccccccccccccc}
 & H & H & H & H & H & H & H & H & H & H & H & H & H & H & \\
H- & C- & C- & C- & C- & C- & C- & C- & C- & C- & C- & C- & C- & C- & C & -H \\
 & H & H & H & H & H & H & H & H & H & H & H & H & H & H &
\end{array}$$

that the maximum number of hydrogens per molecule is two plus twice the number of carbons. No carbon except the two at the ends of the chain can hold more than two hydrogens because two of its four bonds are occupied in holding the chain together. Each of the two end atoms holds three hydrogens.

The only way for a paraffin molecule to increase its oxygen content is for an oxygen atom to replace two hydrogen atoms or for a hydroxyl group O H to replace one hydrogen atom. In the former case, the hydrogen content is decreased and in the latter, it remains the same. If one O H group replaces a hydrogen in $(C_{12}H_{26})$ we should have $(C_{12}H_{26}O)$.

If one oxygen atom alone is placed within the molecule, it must replace two hydrogen atoms in order to find bonds for its two valencies. This would give us two hydrogens less than we had to begin with and the formula would be $(C_{12}H_{24}O)$.

It is thus highly improbable that one can have a compound with the formula $(C_{12}H_{28}O)$

If n had any value greater than unity, the case would be even worse because this would mean a molecule consisting of two or more groups of $(C_{12}H_{28}O)$ and one valence bond of each group would be occupied in holding the two together. The possible number of hydrogens too would be still further decreased. One of the first two terms of the formula must be incorrect or Mr. Del Mar has a new arrangement of the oxygen atom with valency greater than two or a carbon atom with valency greater than four. The only case I've ever heard of before where oxygen has a valency greater than two is in the so-called oxonium compounds; and I think it is true that the science has never known a case of carbon with valency greater than four.

Of course, Mr. Del Mar may not mean his formula as that of a chemical individual, but merely gives it to indicate the proportions of carbon, hydrogen and oxygen in a mixture of substances which he found in a cable. If we allow mixtures, we can mix the original oils in the cable in many ways which would give us any specified ratio of carbon to hydrogen from the ratio one-to-four to the ratio infinity; and we could add air, moisture, or moisture and air, to take care of any amount of oxygen from zero to whatever number of oxygen molecules there are in a cable.

It is fairly well known that mineral oils usually used in cables consist of mixtures of several hydrocarbons of various carbon contents.

For example, suppose we had any number of molecules of normal hexane C_6H_{14} and half of the same number of oxygen molecules in a mixture which we shall call A. The proportions of carbon, hydrogen and oxygen would be 12 to 28 to 1 as Mr. Del Mar indicates.

Or suppose we had any number of molecules of normal dodecane $C_{12}H_{26}$ mixed with an equal number of water molecules H_2O. Let us call the mixture B. The proportions of carbon, hydrogen and oxygen would again be 12 to 28 to 1.

Any mixture consisting of any amount of A with any amount of B would obviously still have carbon, hydrogen and oxygen in the proportions 12 to 28 to 1. Such a mixture we should properly call X, following Mr. Del Mar's happily selected notation.

Let us assume a cable oil with 0.1 per cent each of hexane and dodecane. One gram of this oil would contain 0.001 gram of each substance. Let p be the actual number of molecules of hexane and q the number of molecules of dodecane in 0.001 gram. Then

$$p = \frac{N}{86.112 \times 1000}$$

and

$$q = \frac{N}{170.208 \times 1000}$$

where N is Avogadro's number, Millikan's value of which is $(6.062 \pm 0.006) \times 10^{23}$ and 86.112 and 170.208 are the molecular weights of the two substances. One can have then a mixture of any number of molecules from (1 to p) of A with any number from (1 to q) of B and still have the proportions of carbon, hydrogen and oxygen indicated by Mr. Del Mar. The number of possible different kinds of X, no two of which are identical and each of which would fit Mr. Del Mar's formula is

$$p \times q = \frac{N^2}{86.112 \times 170.208 \times 1000 \times 1000}$$

or

$$p\,q = 2.5 \times 10^{37}.$$

The formula indicates no way except by guessing to tell which of the possible mixtures it represents. If each of the one hundred and ten million people in the United States would make a thousand guesses a day for fifty years this would be 2×10^{15} guesses. The chance of one of these guesses coinciding with Mr. Del Mar's X is a little less than one in 1.25×10^{22} or in other words one in twelve and half thousand billion billion and the guessing would be further complicated by the 99.8 per cent of the oil which we did not consider specifically in the above p and q.

C. F. Hanson (communicated after adjournment): In some localities, high-voltage cables operate at relatively low temperatures. From the point of view of dielectric loss and the possibilities of cumulative heating, these low temperatures of operation are considered favorable. However, from the point of view of internal vacua, these low temperatures are detrimental, if the cable is not permitted to "breathe."

The conditions upon which I base my calculations in arriving at the foregoing conclusions are as follows:

1. The maximum operating temperature of the cable insulation during summer months is 40 deg. cent. (104 deg. fahr.)

2. The minimum operating temperature of the cable insulation during winter months is 20 deg. cent. (68 deg. fahr.)

3. The temperature of the cable insulation at the time of installation during summer months is 30 deg. cent. (86 deg. fahr.)

4. The temperature of the cable insulation at the time of installation during winter months is 15 deg. cent. (59 deg. fahr.)

5. It is assumed that an internal pressure of one atmosphere is established throughout a length of cable while the ends of the cable are open for splicing purposes.

6. The impregnation of the cable is expressed in terms of per cent of air by volume based upon the total air in the cable prior to impregnation. The air content is considered to be that which prevails at 25 deg. cent. (77 deg. fahr.)

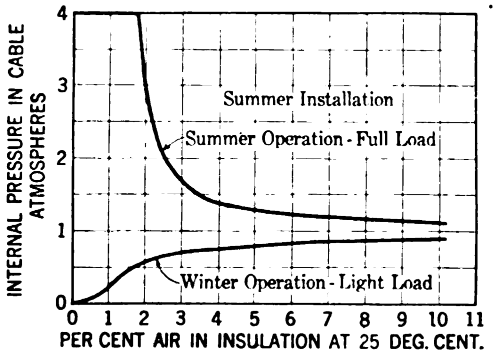

Fig. 2

7. The temperature coefficient of expansion of the impregnating compound is considered to be 0.1 per cent per deg. cent.

8. The internal pressure in the cable which will cause a permanent stretch in the lead sheath is considered to be 4 atmospheres. (Approximately 44 lb. per sq. in. gage pressure.)

9. The impregnating compound and the fibers of the paper are considered incompressible.

10. The temperature coefficient of expansion of the lead and of the copper is considered negligible, particularly in view of the fact that an expansion in the lead is partly counteracted by a simultaneous expansion in the copper conductors.

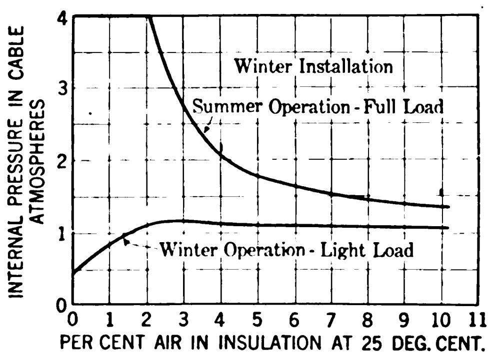

Fig. 3

11. A length of cable is considered sealed at each end by virtue of a non-flowing splicing compound.

12. The volume of air varies according to Boyle's law in regard to pressure.

13. The volume of air varies according to Gay-Lussac's law in regard to temperature.

Within the foregoing conditions, I have calculated for various percentages of air, the internal pressures which will prevail in a cable during maximum load in the summer and during minimum load in the winter when the cable is installed during summer months. The results of these calculations are shown in Fig. 2 herewith. I have also made corresponding calculations for a cable which is installed during winter months, and show the results in Fig. 3.

In Fig. 2, the lower curve shows that the internal pressure of the cable is always less than atmospheric during light loads in winter. If the ionization voltage of air is proportional to the pressure, then it is evident from this curve that a poorly impregnated cable is superior to a well impregnated cable. For example, if, in a cable of a particular wall and voltage, the ionization pressure is 0.8 atmosphere, then the cable having an air content of five per cent or more would operate without ionization. On the other hand, the cable having an air content of less than five per cent would operate during winter months with ionization which will produce carbonization.

If cables are installed during winter months, then operating conditions are more favorable in regard to internal pressure. A cable would have to be well impregnated before its internal pressure would be less than one atmosphere during winter operation. For example, only those cables having an air content of less than 1.5 per cent would have an internal pressure of less than one atmosphere during light load in winter. The reduced pressure in this case is brought about by a permanent stretch in the lead sheath. The permanent stretch is produced during heavy-load periods in summer.

A comparison of Figs. 2 and 3 indicates that when non-flowing splicing compounds are used, winter installation is more desirable than summer installation. Furthermore, the curves in these illustrations, indicate that cables deteriorate mostly in winter, particularly if the cables are installed in summer.

It is not advocated that cables should always be installed during winter months. Winter installation is only a means for partly alleviating the unfavorable conditions caused by the use of non-flowing splicing compounds. The proper installation is that which will permit a cable to "breathe" as the temperature of the cable changes. Such installation is exemplified in the present-day use of very liquid splicing compounds and the application of syphons.

W. A. Del Mar: The principal discussion of my paper has taken place in the personal meetings and correspondence before and since the Madison meeting, and I have been surprised and gratified by the great interest manifested.

As I intimated in my paper and as repeated by Mr. W. S. Clark, there is nothing new in the basic ideas presented, but the implications which bear on ordinary cables seem to have been ignored almost completely by operating men and manufacturers alike. If any manufacturer had these ideas clearly in mind, his duty to the industry was to pass them on without delay to the cable users. So far as I know, this was done for the first time when I gave copies of a memorandum on this subject to several members of the Underground Systems Committee of the N. E. L. A., nearly a year ago.

We all recall the classic 1919 papers by Shanklin and Matson,[2] and Dubsky,[3] wherein it is shown that films of air entrapped in a cable ionize at an insulation stress of about 19 kv. per cm., but perhaps we neglected to note, as the three authors named above were silent on the subject, that this stress applies to air at atmospheric pressure only.

We recall, moreover, the work of such experimenters as Peek, proving that the ionization stress of air is approximately proportional to the air pressure.

Combining these researches, we obtain Table I, showing the

2. Transactions A. I. E. E., 1919, p. 489.

3. Transactions A. I. E. E., p. 537.

relation between ionization stress in cable insulation, and air pressure.[4]

We are now equipped with an important tool which, in our hands three years ago, might have saved the electric power industry and the cable manufacturers a considerable amount of worry. In order to understand this, consider the matter in Table II, which shows the maximum stresses for several typical triplex cables and the air pressures required to prevent ionization at these stresses, taken from Table I. The table may be summarized in a few words:

Cables of the 13,000-volt class do not ionize even though the pressure may be somewhat below atmospheric.

Cables for 22,000 volts have an ionization pressure of about one atmosphere.

Cables for all higher voltages as listed require an internal pressure of between one and two atmospheres. This is a conclusion of great importance which seems to have escaped the attention of the industry. It is well known that cables for over 22,000 volts belong in a different class, from an operating standpoint, from those for lower voltages. The former have had either excessive failures or at least show deterioration of the insulation, except in a small minority of cases. The latter give little or no trouble.

TABLE I

Air pressure, atmospheres	Relative ionization voltage as fraction of that at 1 atmosphere (Peek)	Ionization stress taking 19 kv./cm. for 1 atmosphere
0.1	0.2	3.8
0.2	0.3	5.7
0.5	0.53	10.0
0.7	0.70	13.3
1.0	1.00	19.0
1.25	1.22	23.2
1.50	1.44	27.4
2.0	1.90	36.1
2.5	2.35	44.7

TABLE II
TRIPLEX 350,000-CIR. MIL CABLES

Working voltage between phases, Kv.	Insulation each conductor, 64ths in.	Maximum stress, kv./cm.	Internal pressure required to prevent ionization, atmospheres
13	12	16	0.8
13	9	19	1.0
22	19	20	1.0
22	18	21	1.1
24	18	23	1.25
26.4	18	25	1.35
27.6	19	25	1.35
33	19	30	1.65
33	23	26	1.40

Similar information for single-conductor cables is given in Table III, from which it appears that cables for 132-kv. circuits with 60/64-in. insulation require about 3½ atmospheres, which is near the limit of strength of an ordinary lead sheath.

It is also a curious fact that the trouble seems to increase the more carefully the cable is made. This is because of the difference in impregnation; the more thorough this is, the greater the vacua due to contraction. This has been very clearly brought out by Mr. Hanson's discussion. For this reason, some of the cables of five years ago seem to be more reliable than those of today.

4. If the air films are very thin, this relation does not hold; but experience shows that it is approximately correct for most of the films of the dimensions found in cables.

The effects of ionization in the order of their occurrence are—formation of *X*, carbonization of oil, formation of dendritic patterns, and eventually failure. The action may, however, stop at any point, as cables are in operation which have been full of *X* for years and carbonized oil has been known to exist for years in cables without further deterioration, probably because of increased internal pressure.

Let us consider what has been done by operating engineers to influence the internal pressure of high-voltage cables.

First, they have written specifications which compel the furnishing of "over-saturated" cables, *i. e.*, cables in which high vacua are formed if operated as they have been in the past.

Second, they have done most of their installation work in summer, thereby insuring the occurrence of vacua in winter.

Third, until recently they have used splicing compounds which seal each length of cable and make pressure equalization impossible.

Fourth, they have given no consideration to the installation and operating conditions which influence internal pressure, thereby leaving the pressure to take a chance value which might or might not permit their cable to survive.

It seems necessary to put a definite predetermined pressure on high-voltage cable insulation and maintain it with scrupulous care. Forward-looking practise points to the use of spindle oil splices and syphons. I believe that by this means some cables which have had their operating voltages lowered due to continual failures will be successfully restored to their rated voltages.

TABLE III
SINGLE-CONDUCTOR 500,000-CIR. MIL CABLES

Working voltage to ground, Kv.	Insulation, 64ths in.	Maximum stress, kv./cm.	Internal pressure required to prevent ionization, atmospheres
23	40	24	1.3
26	40	27	1.5
43	52	38	2.1
43	60	35	1.9
76	60	62	3.4

When all high-tension cables are equipped with pressure gages and pressure-maintaining devices, the guarantee clauses in cable specifications will assume a legitimate significance. Mr. Petersen sensed this point very clearly in his discussion.

I agree with Mr. Dunsheath that all high-tension cables do not have to be supplied with special oil ducts, as it is possible to maintain adequate pressure in most cases by relying upon natural interstices in the cable.

My paper supports Mr. Halperin in his views about transient voltages, by furnishing an explanation of certain failures which, in the past, have been blamed on transients.

Mr. Petersen's explanation of the higher breakdown voltage of short lengths as compared with complete feeders,—namely, that oil from the terminal tanks is sucked into the cable,—cannot be correct, both because the opposite action occurs due to the heating of the cable, (*i. e.*, the cable oil is expanded and driven out), and because the same relation holds if the short lengths are tested without oil terminals or tanks.

Mr. Brownell has brought out an interesting point in mentioning that *X* forms more readily at 26 kv. in service than at 100 kv. in the laboratory.

Mr. Davidson seems to have taken my formula for *X* more seriously than I had intended. I used a formula only because the results of analysis as percentages are hard to visualize. The

evidences of polymerization are to be found in high specific gravity, solidity, insolubility, and infusibility considered in connection with the known origin of the material.

Mr. Duncan's discussion of my formula for X is very much to the point. He shows clearly that the suggested formula is untenable, and I am rather inclined to believe that the explanation is that the oxygen atom is superfluous. We can now form X in such vacua that it seems that no atmospheric element can enter into its composition. The chemists obtained the oxygen by difference and not by any positive test, so that its existence is at least open to doubt. The formation of X is preceded by an apparent increase of surface tension, *i. e.*, the oil acts as if its surface tension had increased very greatly, causing it to form into drops. Perhaps the polymerization which characterizes X formation is a result of this surface tension; *i. e.*, it may be nothing but a further drawing together of the molecules.

Mr. Roper's and Mr. Halperin's discussions add important material to our general store of knowledge on this subject. There are more of this kind of data which bear on pressures and vacua in cables to be gathered from the experience of operating engineers. For instance, it has been found that splices which are equipped with unweighted syphons have a lower breakdown voltage than identical splices without the syphons, and some people would interpret that as indicating that the syphons might be an objectionable feature. The explanation as furnished by one of the earliest users of syphons is that splices tested with them are at atmospheric pressure inside, whereas those tested without them, being heated by the dielectric losses, have an internal pressure which may be very considerable. The internal pressure naturally increases the dielectric strength and raises the breakdown voltage at the splice. The obverse of this is seen in the trouble experienced with both cables and joints where vacuum joints have been used.

A full realization of the significance of cable vacua and pressures should materially assist in the design of cables for much higher voltages than now considered practicable, without departing from the diameters which ducts and handling difficulties now impose.

Discussion at Niagara Falls

CIRCULATION OF HARMONICS IN TRANSFORMER CIRCUITS[1]

(Lennox)

Niagara Falls, N. Y., May 27, 1926

D. C. Prince: There are, in general, two ways of regarding such waves as those set up by commutating devices whether of rotating or static character. Fig. 4, in Mr. Lennox's paper, is typical of the waves encountered. Such a wave may be regarded as made up of a series of constant-amplitude waves of different frequencies, as Mr. Lennox has done, or it may be regarded as a succession of simple states.

From this latter point of view, the wave shown consists of direct-current portions joined by portions of constant slope. Both these states must independently obey Kirchoff's laws. This enables the wave forms, at least in the simpler networks, to be made up, taking into account the various impedances.

In particular, the transition portions of rectifier waves have as their driving force the impressed sine-wave so that the transition currents are sine waves of fundamental frequency superimposed upon either steady or decaying direct currents. These lend themselves readily to quantitative analysis where the harmonic analysis may present some difficulty.

From the point of view of inductive interference, some error may be invited if the analysis method is used. For instance, a square wave under harmonic analysis may give waves of all frequencies which are multiples of the fundamental. Some of the frequencies with the indicated amplitudes might set up objectionable interference. Physically, however, the inductive effect is in the form of impulses sent out at half-cycle intervals. These impulses set up a series of damped wave trains in a resonant circuit or simply a series of pulses in a circuit damped beyond the critical point. Neither of these responses is necessarily objectionable. The difference is that, when a wave is analyzed, the effect of all the components must be included. Many of these will have cancelling effects which might be lost sight of in treating any given problem by harmonic analysis.

A FLUX-VOLTMETER FOR MAGNETIC TESTS[1]

(Camilli)

Niagara Falls, N. Y., May 27, 1926

R. L. Sanford: For the determination of the average value of an alternating electromotive force a rectifier of some kind is necessary. While somewhat difficult to keep in good working condition, the rectifying commutator, either mounted directly on the generator shaft or driven by a synchronous motor, has been, up to the present time, the only satisfactory apparatus for the purpose. The commutator has a number of disadvantages which are obvious to any one that has had occasion to use it and the development of a really satisfactory method for measuring average volts represents a distinct advance in the art.

The device described by Mr. Camilli has the advantages of simplicity and portability. While the evidence of its reliability presented in the paper seems to be fairly conclusive, it was felt that a really crucial test would be a direct comparison with the rectifying commutator using a sine wave of voltage and also with various degrees of distortion. This was done at the Bureau of Standards. In making the test, the commutator brushes were adjusted for rectification at the zero point on the wave and its condition was checked by noting that the reading of an a-c. voltmeter was the same whether connected to the source directly or through the commutator. The average volts were read by means of a Brooks deflection potentiometer and a volt-box. Simultaneous readings were taken by different observers with the potentiometer and the flux voltmeter, and the values in all cases agreed well within the limits of the allowable error. It appears, therefore, that the flux voltmeter measures average volts with a satisfactory degree of accuracy and should prove to be a very useful instrument for a number of purposes.

As pointed out by Mr. Camilli, the total core loss with a distorted wave is somewhat high, as the eddy-current loss is proportional to the square of the effective voltage rather than to the average voltage. He has indicated an indirect method for making the correction. It would appear better, however, to determine the correction directly by making measurements with different degrees of distortion, noting the effective voltage in each case. The correction can then be made by simple calculation. This method has the advantage that no assumption as to the ratio of eddy currents to hysteresis is necessary.

W. H. Cooney: Any one who has endeavored to obtain a given core loss twice on the same transformer when using different generators on each test with consequent variations in wave form will appreciate the development of a meter which will give consistent results regardless of how distorted or how near sine wave the wave form is.

In the past, many core-loss correction outfits have been based on setting voltage by an a-c. voltmeter, thus getting the r. m. s. value. Since, as Mr. Camilli pointed out, only the eddy loss is a function of the r. m. s. value, the correction which had to be made was almost entirely in the hysteretic component. That this was not the proper end from which to tackle the problem can be realized by considering the general proportion of hysteresis and eddy losses.

1. A. I. E. E. Journal, August, 1926, p. 755.
1. A. I. E. E. Journal, October 1926, p. 989.

Eddy losses are very rarely more than 20 per cent of the total loss and are usually much less. By the use of this scheme, which holds the average voltage corresponding to the effective sine-wave voltage desired, the correct hysteresis loss is maintained and the correction need be made only on the eddy component, which, as has been said before, is comparatively small.

Some of the previous core-loss corrections consisted essentially of a small "standard" transformer excited in parallel with the transformer under test, and one of two methods was used: (1) The available voltage was varied until the "standard" transformer held the desired core loss; or (2) the available voltage was adjusted to the desired root-mean-square value (regardless of the wave form) and the loss of the transformer under test was corrected in the same proportion in which it was necessary to correct the "standard" transformer in order to put the latter on a sine-wave basis.

The objections to the use of a small "standard" are quite apparent. The chief objection is that the "standard" is very seldom at the same density as the main transformer and thus is not operating on the same part of the density-loss curve which has a decided "knee" in it. It is necessary to maintain all sorts of calibration curves with the increased liability of introducing errors. There is finally the general objection that a small model in tests of this sort cannot be expected to duplicate the phenomena occurring in large apparatus.

The only correction which needs to be applied to this meter (for eddy loss) can be made very easily, as very few calibration curves will be necessary since the division of hysteresis and eddy losses can be determined closely enough for any given line of steel. The only possible case in which this meter will be inaccurate is where the wave goes through zero more than twice in a cycle, and this should never occur in commercial testing.

Aram Boyajian: The simplicity of the theory, construction and method of application of the flux voltmeter may tempt us to underestimate the excellent engineering which has been incorporated into this outfit. It is true that such parts of the outfit as d-c. voltmeters and vacuum-tube rectifiers have been available separately, and it is also true that the mathematical relation between maximum flux density and arithmetical average voltage has been known to the electrical art for a long time. It remained for Mr. Camilli, however, to bring together the theory and these pieces of apparatus into an outfit which accomplishes a new function in a new and very satisfactory manner. The accuracy and consistency of core-loss tests made with the aid of this outfit are surprisingly good, especially in comparison with the older schemes. The extent to which the older schemes underestimate the core loss under conditions of bad wave distortion will no doubt interest very strongly inspectors on acceptance tests as well as those engineers who draw up specifications.

T. C. Lennox: I should like to point out the advantage of this device for determining the core losses in interphase transformers for rectifiers. These interphase transformers have voltages which are not of sine-wave form and furthermore have different wave forms for different conditions of load so that it is difficult to obtain loss measurements which are representative of actual losses under load. The flux voltmeter could be very easily applied to obtain the actual flux densities under load conditions and thus aid greatly in obtaining a correct measurement of the efficiency of the equipment as a whole.

CURRENT TRANSFORMERS WITH NICKEL-IRON CORES[1]

(Spooner)

Niagara Falls, N. Y., May 27, 1926

I. F. Kinnard: In the design of current transformers, it has long been recognized that a core material having low losses and high low-induction permeability is desirable. It is undesirable, however, to have the permeability of a transformer core changing very rapidly over its working range.

Wonderful strides have been made in perfecting magnetic materials in recent years. The material described recently by Messrs. Arnold & Elmen[2] known as "permalloy" has properties which recommend it very highly for the use Mr. Spooner has outlined. Mr. Spooner has not given us any specific magnetic or metallurgical data on hypernik, but it probably can be assumed that it is very similar in its properties to the series of iron-nickel alloys described by Yensen[3].

Permalloy in particular, and, to a lesser degree, other iron-nickel alloys, partially fulfill the requirements of an ideal core material. The reason they do not more completely fulfill these requirements is largely due to their rapid change in permeability. In fact, at a fairly low induction the permeability falls off so rapidly that the accuracy of the transformer is seriously impaired, as pointed out by the author. This is particularly troublesome in the through-type or bushing transformers where the operating density is necessarily high with secondary burdens usually met with in practise.

It is to be hoped that further improvement may make it possible to utilize the remarkable properties of these various alloys to greater advantage; that is, that their range of usefulness may be extended to transformers having less than 200 ampere-turns which will operate secondary burdens up to at least 15 or 20 volt-amperes.

I am interested in Mr. Spooner's description of utilizing the coordinate a-c. potentiometer for measuring the magnetizing and watt components of the exciting current. This is a big improvement over most methods used in the past. I believe it is possible to extend this general method so that a strictly null setting may be obtained and the possible accuracy made even greater. We must not lose sight of the fact, however, that the real criterion of a transformer's performance is the precision measurement of its ratio and phase angle.

Several laboratories are equipped to measure these quantities directly to a higher degree of accuracy than we can hope to reach by their calculation from a knowledge of exciting current and magnetic properties.

W. K. Dickenson: The ideal toward which every instrument-transformer engineer is working is to obtain a minimum error in the ratio of transformation of voltage or current, particularly that part of the error commonly called the phase angle, which is caused by the secondary voltage or current not being in exactly 180-deg. phase opposition to the primary voltage or current.

In current-transformer design, this has usually been accomplished by the use of a relatively high number of ampere-turns (usually 1000 to 2000) and by a considerable cross-section of core iron. This materially limits the use of the through-type or single-turn-primary type of transformer, since, as there is only one turn available, the current has to be 1000 amperes or more to give a sufficient number of ampere-runs for a good transformer.

A very considerable improvement in the characteristics of transformers, particularly current transformers, has been obtained by the now very common use of silicon steels. It is very encouraging to note the further improvement in both the ratio and phase-angle errors by the use of high-permeability steels, such as hypernik and other nickel-alloy steels, such as nicaloi or permalloy. Mr. Spooner has shown that not only can the ampere-turns be reduced (he states a minimum of 200 ampere-turns) but the weight of core can also be reduced by the use of hypernik.

As pointed out by Mr. Spooner, however, it is to be regretted that only low secondary burdens may be operated by transformers having cores of these nickel-alloy steels, because of their characteristic of becoming saturated at quite low magnetic

1. A. I. E. E. Journal, June, 1926, p. 540.

2. *Journal* Franklin Institute, May, 1923, pp. 621-632.

3. A. I. E. E. Transactions, 1924, p. 145.

densities. It is unfortunate that in the particular application where the through-type or single-turn, primary type of transformer would be of greatest value, *viz.*, in large power stations, the secondary burden is likely to be fairly high, due to the necessary length of the secondary leads. These leads are seldom less than 100 ft. in length (200 ft. No. 10 A. w. g. wire equals 5 volt-amperes) and in one of the new stations in New York City the secondary leads are 1000 ft. in length, 2000 ft. of wire (50 volt-amperes for No. 10 A. w. g. wire).

It is to be hoped that means may be discovered that will enable us, through a wider range, to take advantage of the very encouraging results obtained by Mr. Spooner by the use of nickel-iron alloys.

Thomas Spooner: Mr. Kinnard is correct in assuming that hypernik is a nickel-iron alloy. The nickel content is approximately 50 per cent. Hypernik, however, is a very special alloy, in that it is made from very pure raw materials in a type of electric furnace which permits of no contamination. After being rolled to the proper thickness it is given a special, somewhat expensive heat treatment which was developed for this particular material.

Mr. Kinnard has perhaps misunderstood my purpose in using, to a large extent, calculated instead of test values for current-transformer performance. It was first shown that for through-type transformers, this is a reliable procedure. The calculated performance for a number of sizes of transformers was then determined, since this is much quicker than actually constructing the transformers and then testing them. If transformers are actually to be built, it is of course better to measure than to calculate their errors if accurate results are desired in order to take care of variations in the core material and, in any but through-type transformers, of the effect of joints in the magnetic circuit and of magnetic flux leakages.

Referring to Mr. Dickenson's remarks, while it is true that the nickel-iron alloys saturate at a considerably lower induction than do the silicon steels, the permeability of hypernik is nevertheless higher than that of the best laboratory-prepared silicon steel up to an induction of five or six kilogausses. This corresponds to a fairly large secondary burden, even for low-ratio through-type transformers, thus making hypernik superior to silicon steel even under these adverse conditions.

THE RETARDATION METHOD OF LOSS DETERMINATION AS APPLIED TO THE LARGE NIAGARA FALLS GENERATORS[1]

(Johnson)

Niagara Falls, N. Y., May 28, 1926

R. B. Williamson: The testing of large generating units after they have been installed in the power station is becoming more common than was formerly the case because the great increase in size has rendered satisfactory factory testing very costly; in many cases it is, in fact, impracticable because the machines are not completely wound and assembled at the factory. There is no doubt that a great deal of money has been expended in the past on unsatisfactory factory tests that could have been made to much greater advantage after installation. Any methods of testing, therefore, that are of advantage when machines have been set up ready for use are worthy of very careful study and we are much indebted to Mr. Johnson for the present paper which shows the application of the retardation method to some of the largest hydroelectric units so far built.

In factory testing the usual method of determining losses is by means of a calibrated driving motor, but this is often difficult to apply to large vertical units. When using a driving motor it is frequently difficult to hold the source of power steady enough to avoid periodic swings in the power input to the motor and this affects the accuracy of the readings. When large machines are tested in the power house by measuring the input with the generator operating as a motor supplied from a second water-wheel unit, the source of power is much steadier and correspondingly better results can be obtained. Even here, however, difficulties are sometimes met due to periodic variations caused by slight hunting of the water-wheel governor. One great advantage of the retardation method is that, after the machine has been run up to or slightly over speed, the driving power is cut off and all fluctuations due to variations in driving power are also cut off.

In applying the method to water-wheel units where it is necessary to leave the wheel connected and thus rotate the runner in the water-wheel casing, it is important that the casing be drained and also opened by removing the manhole covers. I recall one instance where a retardation test was being made and unaccountable variations were found in the speed. The casing had presumably been drained but the vents had not been opened and it was found that a considerable quantity of water was being thrown around in the casing. The manhole covers were then removed, the casing completely drained well below the level of the runner, and there was no further trouble.

As pointed out by Mr. Johnson, it is not essential that the fly-wheel effect of the rotating parts be known in advance provided means are at hand for measuring the kilowatts required to drive the machine as a motor at known speed. If the loss is thus measured, the fly-wheel effect for use in the other tests can then be calculated with a sufficient degree of accuracy. Usually, however, there is no difficulty in obtaining a close estimate of the fly-wheel effect from the manufacturer and the retardation tests are sufficient to obtain the losses by the methods described.

The analysis of the friction and windage of the three 32,500-kv-a. units in Table IV is of special interest. Unit *A X* as mentioned is equipped with shrouded steel-plate fans with curved blades, and baffles are provided to prevent eddies and short-circuiting of air around the fan. On account of the limitations imposed by the generator design, these fans have an efficiency considerably lower than that of regular blowers provided with a spiral casing, but at the same time it is true that a generator of this type with such fans and baffles will show in general less windage loss than one where the air is free to eddy around. Where the peripheral speed of the rotor is fairly high, as in the present instance, the difference in windage loss may be considerably in favor of the machine with fans as in Table IV, whereas the general feeling of many users is just the opposite, *i. e.*, that fans increase the windage loss. The spider arms of large generators stir up vigorous air currents which involve loss in power; hence shrouding the arms to cut off these currents is frequently well worth while.

It is of special interest to the designer to note that these tests indicate that the stray-load loss at a given speed varied as the square of the current. This, I believe, has been generally assumed to be the case and tests on many machines made by driving by means of a calibrated motor show this relation to be quite closely true. It is important, however, to have this confirmed by tests made on such a large generator and by a different method. The greater part of the stray loss is undoubtedly due to so-called eddy currents in the windings, but a considerable part is also due to stray induced currents in various parts of the machine structure caused by stray fluxes from the windings. It is fortunate, therefore, that notwithstanding the complicated make-up of the stray loss, it is found to be practically proportional to the square of the current.

We fully agree with Mr. Johnson that with the use of suitable instruments, such as he describes, the retardation method can be made of much more use than has been the case in the past. We also feel sure that with the more extended use of methods such as these, tests of machines after installation will supersede many of the factory tests now made on large or even moderate-sized

1. A. I. E. E. Journal, June, 1926, p. 546.

units, because such tests will be less expensive and very much more satisfactory.

E. M. Wood and G. D. Floyd: At the Queenston plant of the Hydro-Electric Commission, we have had the same problem of determining the conventional efficiency of large water-wheel driven alternators, and have in general solved it in a manner similar to that described by Mr. Johnson. Some of our conditions have been different from those described and have given rise to variants in the procedure, some of which may be interesting.

All our tests were made with the turbine uncoupled from the unit under test, as the units have two guide bearings. The units were started as described in the paper. Field current for approximately normal voltage at no load was required on each of two similar units for sure starting. Starting currents at times swung to ½ rated current of one generator of 55,000 kv-a. rating.

Manufacturers' calculations of $W R^2$ were taken but were checked by wattmeter measurement of input to the unit as synchronous motor, whenever the governor of the driving unit would hold speed sufficiently steady to give reliable readings. The calculation checked closely with the test values.

When conditions permitted this test, however, a complete curve of losses by wattmeter was taken down to approximately half voltage. Under proper conditions, these results are possibly more dependable than those from the retardation test but in most cases (but not all) the governor allowed the speed to hunt so that the results were of doubtful value.

The current transformers used were rated at about four per cent of the current rating of the generator and were connected across the blades of gang-operated disconnecting switches to protect them during starting and during changes of test conditions. A man was stationed at the switch with an ammeter and given instructions to close the disconnects quickly in case of a sudden rise of current.

On the first units tested, retardation tests were made using a stop watch and hand tachometer, varied by use of a tachograph and in some cases by use of a high-speed graphic voltmeter for the core-loss curves. We found these not very satisfactory for the reasons stated in the paper.

On the last three units tested, a Cambridge chronograph adapted by Messrs. Borden and Floyd was used. Two elements record on a tape the following:

1. One jog for each half-revolution of the generator.
2. One jog for each revolution of a machine running at synchronous speed (187½ jogs per minute).

From the tapes, speed-time curves were plotted, the rate of retardation at synchronous speed was found and the losses calculated. The average loss between one per cent above and one per cent below synchronous speed was calculated directly in most cases, as the average speed-time curve had been obtained very accurately between 110 per cent and 90 per cent of synchronous speed. In those cases where a curve of loss against speed was obtained, the loss at synchronous speed checked the calculated loss very closely.

The method of reading the record, tabulating the results and calculating the losses given in the paper is very neat and simple. The long intervals were apparently allowable due to the high fly-wheel effect and slow retardation. In our case, the intervals had to be much shorter. This could be varied by using longer overlapping intervals.

Curves of friction, windage and short-circuit losses were taken on one of our units by the retardation method with good results. The switching incident to this test is somewhat involved and must be carried out in a very short time, requiring careful preparation. In this test, it is of importance to observe the temperature of the armature windings.

Mr. Johnson's practise of running the retardation test to below 50 per cent of rated speed is new, and he has used it to obtain much interesting information.

V. Karapetoff: I am glad to hear a practical operating man recommend the retardation method because I have been urging its use for over 20 years. I learned about it in Europe where it has been used much more than here. The principal reason why, perhaps, it has not been used so much is that with small machines the rotating part stops too rapidly to allow an accurate measurement of retardation, and the second reason is the necessity for knowing the moment of inertia.

Of course these difficulties are not insuperable and those interested in this method will find both in the Continental and in the British literature, quite a number of ingenious and indirect methods of measuring deceleration and the moment of inertia. The general theory will be found in my *Experimental Electrical Engineering*, Third Edition, Vol. I, pp. 408-416.

Mr. Johnson suggests that a convenient and simple method be developed for directly measuring the rate of retardation. I wish to mention a condenser device which was proposed quite a number of years ago for measuring acceleration and deceleration of railway trains, and which, with modern measuring instruments, should be satisfactory for the purpose desired. Consider a capacitor connected to a source of direct voltage. Then we have the relation: $q = C e$, where q is the charge on the condenser, C is its capacitance, and e is the applied voltage. Taking a derivative of both sides of this equation with respect to time, we get $d q/d t = C d e/d t$. Call this current i; then $i = C d e/d t$.

Suppose that you have some device, such as a d-c. magneto generator, belted or otherwise connected to the generator under test, and let the induced voltage of this device be proportional to its instantaneous speed. Then $e = k v$, where v is the instantaneous velocity, and k a coefficient of proportionality. Substituting this value of e in the equation for the condenser current, we find that $i = C k (d v/d t)$.

The value of $d v/d t$ is the retardation of the machine, and the current flowing into or out of the condenser is proportional to it. In other words, if you have a magneto in series with a galvanometer and a condenser, the instantaneous indication of the galvanometer is a direct measure for the instantaneous retardation of the machine.

W. J. Foster: Mr. Johnson has described the retardation test and he has developed it, I think, to a higher degree of perfection than any other person.

There are three methods of testing large generators: the motor method, the retardation and the calorimetric. The first that I had experience with was the motor method and fairly good results were obtained, but it failed completely in the matter of the load losses or short-circuit losses. Since those losses have become very important the motoring method by itself is now obsolete.

The retardation method was developed and practised several years ago quite extensively in the shops of the General Electric Company. It was found to be a very convenient method when the speed could be determined with accuracy and the $W R^2$ from calculation, but when the rotor contained castings there were always some uncertainties about the $W R^2$.

In our work we sometimes found it well to obtain the speed electrically, which is especially easy where there are direct-connected exciters and a battery is used to excite the field so as to hold the excitation perfectly constant.

I regard the calorimetric method, however, as the coming method in most machines. Our hydraulic generators are going to become more and more totally enclosed and it is not in the far distant future when we will have the closed system, the same air being returned over and over again. So I think that the most accurate method and the method by which we will obtain the real efficiency will be the calorimetric method.

I say the real efficiency because the matter of taking the short-circuited losses as the load losses is an approximation to accuracy. It has been standardized and when it is used by the designers in calculations and in giving guarantees it, of course, should be measured in the test, and the total losses should include for load

losses the short-circuited losses. But by the calorimetric method the actual load losses are obtained and that is extremely important.

I think that in such generators as Mr. Johnson has worked with, where he has housings around them, he can very well check up the results obtained by the retardation method. I wish he would do so as a supplement before this paper is published in the A. I. E. E. TRANSACTIONS. It wouldn't take over two days on one of those machines to do all of it. He should vary the power factor of the machine under test from unity down to 80 per cent, and thus be able to furnish extremely valuable data for designers as well as for users.

I can't speak in too high terms of the work done by Mr. Johnson. I have been in contact with it somewhat and he certainly has used his brains.

It was just a trifle amusing to me to notice his remarks with reference to the unusual opportunities that he had in having three generators of different design and also some combinations of hydraulic turbines to work with.

No doubt the engineers of all of the manufacturing companies will agree that each has some compensation for the disappointment he experienced in failing to receive the order for all three units,—in the excellent test data and the improved retardation method furnished by Mr. Johnson.

Mr. Johnson discusses the effective resistance and gives formula (8). I wish to remind you that there are other losses, eddy-current losses in the magnetic material, and what is needed now is for data to be collected that will look towards the determination of the effects of end magnetization.

P. A. Borden: It is particularly interesting to learn that in his tests of generators, Mr. Johnson has been making use of the chronograph for the precise determination of speeds through a cycle of velocity values. A method almost identical with Mr. Johnson's was developed independently by the Hydro-Electric power Commission of Ontario, and since then has been employed in all its tests of large units where there was required a permanent and accurate record of all speed values during the time of observation.

L. A. Doggett: (communicated after adjournment): In connection with the study of the losses of induction motors supplied with non-sinusoidal electromotive forces, some retardation runs have just recently been made at the Pennsylvania State College. These runs were on machines of 5 to 20 h. p. Although these machines are pigmies compared to Mr. Johnson's 65,000-kv-a. unit, it would seem worth while to have on record some of the problems occurring at the other end of the scale of sizes.

First, as to speed measurements, it soon developed that the attachment of a tachometer, whether of the mechanical or electrical type so altered the friction that the retardation curve was materially affected. For example, where it took 52 sec. to reach zero speed without the tachometer, it took 37 sec. to reach zero speed when a tachometer of the electric type was applied to the end of the shaft throughout the run, all other conditions remaining the same. To avoid this error a stroboscopic method was used, in which an arc was supplied by a current of known frequency. The light from this arc was directed upon a disk attached to the shaft. On this disk were arranged in the usual way circular rows of spots at uniform intervals, such as 45 deg. and 30 deg. The time was noted when these spots reached apparent rest. With this arrangement very satisfactory speed-time curves were obtained.

Second, as to $W R^2$ measurement, this value was determined in two ways. The first is as described by Mr. Johnson and involved a separate measurement of the friction and windage at a definite speed. This in conjunction with the retardation run gives a value for $W R^2$, which for one five-h. p. induction motor was 2.36 lb-ft². A second value was determined by another method. In this method the rotor was removed from the stator and suspended vertically as a torsion pendulum and in this condition its time of swing was determined. The time of swing was again determined when an additional known $W R^2$ was attached to the rotor. From these data the $W R^2$ came out 2.26 lb-ft². The torsion pendulum method is considered the more reliable.

J. Allen Johnson: Several speakers have made suggestions as to the technique of the tests such as the necessity for draining the wheel case and opening vents, the use of disconnecting switches to short circuit the small current transformers during adjustments, etc. These are desirable precautions. Messrs. Wood & Floyd have used a generator running at synchronous speed to measure time. It would seem to the author that much more accurate means of measuring time are available in the form of clock mechanisms.

The electrical accelerometer outlined by Professor Karapetoff is extremely interesting and if it could be worked out into an instrument suitable for field use might be of value. At present it appears to the author as a scheme which might readily be used in the laboratory but hardly a tool for powerhouse use. It has, however, interesting possibilities, and the author looks forward to the time when the inherent merits of the retardation method will have created sufficient demand for such an instrument to justify some manufacturer in undertaking its development.

Anyone who has carried out retardation tests and has observed the almost majestic steadiness with which these huge machines slow down under the influence of their own losses, completely unaffected by any outside influence, will share with him, the author believes, not only his conviction that in this method we have something elemental in its simplicity and trustworthiness, but also his desire for a means of making the necessary measurements of speed and rate of retardation as simple and direct and elemental as the method itself. Such a means seems to be provided in the use of a chronograph, revolution counter and timer. The author doubts if he could have equal confidence in the results obtained by any method less simple and direct, such, for instance, as electrical tachometers or accelerometers involving the accurate knowledge of electrical constants and the necessity of accurate calibration.

Mr. Foster calls attention quite rightly to the fact that in measuring the short-circuit losses we are only making an approximation to the actual stray-load losses. The author frankly recognized this fact in stating in this paper that these tests were to determine the "conventional" efficiencies of the machines in question.

Mr. Foster proposes the calorimetric test to determine the *actual* load losses. The author sincerely hopes that successful results may be obtained in this manner, but confesses to some skepticism in the matter, when recalling a test of this character, in which he assisted, made on a 7500-kw. generator in 1905 or 1906. The losses by radiation, the difficulties in determining accurately the average temperature of large volumes of air and of determining the mass and velocity of the air are a few of the practical obstacles which the author sees in applying the calorimetric method. He agrees with Mr. Foster, however, that no other method of determining the actual stray losses seems possible, and the desirability of finding out what these losses actually are probably justifies considerable trouble in perfecting the calorimetric method. He is of the opinion, however, that nearer two months than two days would be required to get any worthwhile results on the large generators by this method.

Mr. Doggett's method of determining $W R^2$ by using the rotor as a torsional pendulum is very interesting. To apply this method to a rotor weighing 400 tons, however, would seem to invoke some practical difficulties.

VARIABLE ARMATURE LEAKAGE REACTANCE IN SALIENT-POLE SYNCHRONOUS MACHINES[1]

(KARAPETOFF)

NIAGARA FALLS, N. Y., MAY 28, 1926

P. M. Lincoln: It would have added to our information if Prof. Karapetoff had gone a little further into the details of the amount of departure of this particular machine which he cites in the last part of his paper.

The reactance of our large machines is becoming very much larger than it was ten or fifteen years ago. At that time, internal reactance of generators was something of the order of 10 per cent —from 8 per cent to 12 per cent; nowadays, on account of the very much greater capacity of the machines, it is necessary to limit the amount of short-circuit current that will occur in order to secure safety in switching devices. And the best method of limiting of course, is to limit the reactance. The internal reactances of our large generators has gone from a matter of 10 or 12 per cent up to 15 to 25 per cent. It has more than doubled.

Now Prof. Karapetoff has indicated that this much larger internal reactance can be properly divided into two factors. One of them is a reactance which is independent of the position of the phase of the current-carrying coils with respect to the poles, and the other factor is a factor which depends upon that relationship.

I think it would add to the paper if Prof. Karapetoff would indicate the amount of departure between the tests and the assumption that the reactance is constant—how much is ΔL, what is the value of ΔL that he has discovered, what that relation is that it bears to the L.

E. B. Shand: Referring to Blondel's theory of two reactions, assume that the armature conductors of an alternator are carrying current of which the phase relation may be represented by the accompanying Fig. 1; the armature turns are concentric with the field winding so that they will either add to, or subtract

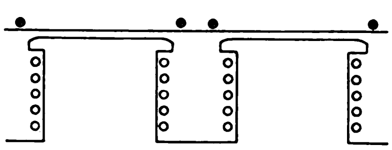

FIG. 1

from, the ampere-turns of the field. This component of current is that of direct magnetization. When the current is 90 deg. out of phase from the above condition, as is indicated in Fig. 2, the flux produced by the armature magnetizing force will pass into one side of the pole and out the other side. Thus flux has always presented some difficulty to me in the way of definition. If the ordinary transformer conception is adhered to, this flux, which

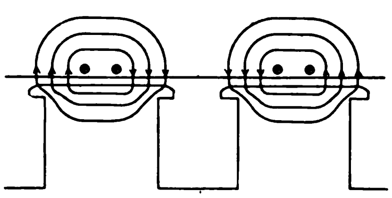

FIG. 2

does not interlink with the field winding, will be called leakage flux. On the other hand, the armature ampere-turns modify very materially the main flux of the machine and also may produce saturation effects so that it has always seemed to me that the definition "cross-magnetizing flux" in accordance with Blondel's ideas is the better term for it.

1. A. I. E. E. JOURNAL, July 1926, p. 665.

Any analysis of the kind given in this paper is greatly dependent upon where the line is drawn between armature cross magnetization and armature leakage reactance. I should like Professor Karapetoff to give us his ideas on this matter and the assumptions he has made in connection with the paper.

J. F. H. Douglas (communicated after adjournment): Professor Karapetoff's article shows clearly how many factors must be considered in theory when accurately predicting the performance of a synchronous machine, factors which do not enter into the performance at zero power-factor.

His treatment of linkages of flux has the merit of rigor which

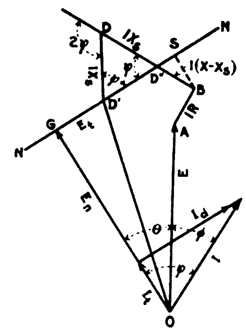

FIG. 3—ILLUSTRATION TO PROVE THAT THE BLONDEL TWO-REACTANCE DIAGRAM IS IDENTICAL WITH THE DIAGRAM INCLUDING A SUPPLEMENTARY REACTANCE DROP

the arbitrary assumption of two "reactances" seems to lack. His equations (8) and (9) in conjunction with his Fig. 1 lead to an important relation

$$X_s/X = \Delta L/2\,L < 1/2 \qquad (1)$$

on which it would be interesting to have an experimental check. He shows clearly that by considering theoretically derived constants X_t and M_d, and the more usually known reactance, $(X - Xs)$, values of the torque angle θ and of the internal phase angle ψ may be considerably in error.

The graphical construction given in his Fig. 3 follows along lines advocated by me in the discussion of an article in the

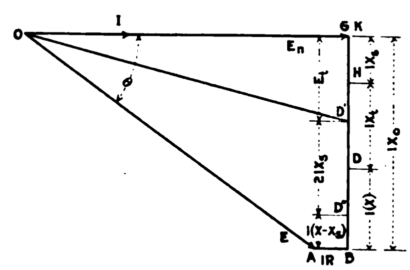

FIG. 4—BLONDEL DIAGRAM FOR CONDITION OF NO DIRECT REACTION

A. I. E. E. JOURNAL for Jan. 1925,[2] with the added advantage, of course, of including the factor X_s.

Fig. 2 of his article is susceptible of interpretation in several ways. It is important to note that one interpretation is not inconsistent with the two-reactance theory in general and that of Dr. C. P. Steinmetz noted in Footnote 4 in particular. Consider the accompanying Fig. 3, which is Fig. 2 in the article with the point S added. The lines $D\,S$ and $B\,S$ are

$$D\,S = I\,(X + X_s)\,\mathrm{Cos}\,\psi = I_t\,(X + X_s) \qquad (2)$$

$$B\,S = I\,(X - X_4)\,\mathrm{Sin}\,\psi = I_d\,(X - X_s) \qquad (3)$$

We may locate the $I\,X$ drop as $B\,D + D\,D'$, or as $B\,S + S\,D'$.

2. Douglas, Engeset and Jones, *Complete Synchronous Motor Excitation Characteristics.*

The latter interpretation of the figure is that the $I\ X$ drop consists of two separate components, (a) one caused by the direct component of the current I_d acting with a reactance, $X_a = X - X_s$, and (b) one caused by the transverse current I_t acting on the reactance $(X + X_s)$.

Another viewpoint might be to regard $S\ B$ as above and consider $S\ G$ as a sort of total transverse voltage drop, due to the transverse current I_t acting on the reactance $X_o = X + X_s + X_t$ using the notation of Karapetoff's equation (**15a**). Inasmuch as

$$X_o = X_a + 2\ X_s + X_t \quad (4)$$

it will be seen that to consider X_a and X_t and neglect X_s may result in considerable error. The graphical construction is in no way influenced by these interpretations but the theory becomes very much simpler, when we consider the constants M_d, X_o, and X_a, and disregard their components X, Xs and $X\ t$.

As is well known, the zero full-load saturation curve can be used to evaluate both direct reaction and armature reactance. The reactance evaluated is, I believe, that reactance I have called X_a, namely $(X - Xs)$. It would be most desirable to have an experimental method for the evaluating of the reactance $X_o = (X + X_s + X_t)$; the experiment which would be most useful would be to load a machine as an alternator, with a leading current such that the angle ψ was zero, that is, with the current wholly transverse. With this loading, the voltage terminal E, the torque angle θ, and the field current should be measured. Fig. 2 of the article then becomes the accompanying Fig. 4 below, and the reactance X_o and E_n can be computed by

$$X_o = (X + X_s + X_t) = (E \operatorname{Sin} \theta)/I \quad (5)$$

$$E_n = E \operatorname{Cos} \theta + I\ R \quad (6)$$

The value of E_n should check with field current I_f if the theory is correct, and the value of X_o could be obtained.

I wish to record the conviction that the attempt to separate Xo into components X, X_s and X_t, will be very difficult. First, physically, where shall we picture the $(X + X_s)$ linkages as ending and the X_t linkages as beginning? Experimentally X_o alone can be measured. If we calculate X_t theoretically from design data, and the residual $X + X_s$ is small, then there will arise the question whether our transverse coefficient is accurately known. For example, the whole effect could be attributed to an error in the theoretical derivation of the constant X_t. Stated in a somewhat different way, I could, with a single value of armature reactance X_a, and a somewhat larger value of X_t than Prof. Karapetoff uses, predict the same performance characteristics that he does, with the use of the three constants X, X_s and X_t. (I am referring to the phase angles θ and ψ, for the field current another constant, that of direct armature reaction would have to be used.)

Vladimir Karapetoff: In reply to Mr. Shand's question, I should say that from a physical point of view we have in an alternator a doubly excited magnetic circuit, which is excited by the field winding and by the combination of the polyphase windings on the armature. There is a complicated flux which varies in space and in time, and only part of which moves synchronously with the poles, the rest corresponding to harmonics moving at different velocities, some in the direction of rotation of the machine, some against it. Any division into various armature reactions and leakage reactances is only a practical makeshift which perhaps is not rational from the physical point of view. The best we can do here is to play the game straight and not figure out the same fluxes twice.[3]

The particular makeshift which Blondel proposed many years ago consists in resolving the armature currents into two components in time, one component which reaches its maximum when that particular group of conductors is opposite the center of a pole and the other group which reaches its maximum in the position midway between the poles. The magnetomotive forces due to these two components are considered separately and also in combination with the field m. m. f. For details see the references given above.

SAG CALCULATIONS FOR TRANSMISSION LINES[1]

(DWIGHT)

NIAGARA FALLS, N. Y., MAY 28, 1926

M. G. Lloyd: I want to say something about the problem in general, and how it has been handled elsewhere. There are two ways in which it may come up.

In a line that is already constructed, if you know what your sag is, you can get the tension very simply by this formula (2) which the author has given and which expresses the tension in terms of the sag, the loading, and length of span.

I think the more usual case, however, comes up in the design of a line where you want to know how to string the wire so that under the worst condition of loading which it will experience or which may be assumed, it will not be stressed beyond a definite fraction of the strength. In that case you start out with your loading and with your definite tension and you want to find the sag. Formula (1) does that very simply for that loaded condition.

The construction man puts it up, however, under some other condition, and he wants to know what the corresponding sag is under stringing conditions, and that is the thing which gives a lot of trouble.

As the author here points out, by using these formulas, one can work back by a method of trial and error or successive approximations, or you can, using formula (3) and others, work out a number of cases and get a set of curves from which then you may be able to read off directly the particular value which you want.

I want to speak, however, of another method of doing that which we have found more simple and time-saving in the long run. And I might say that at the Bureau of Standards I think perhaps we have done as much sag computing as anywhere in the country, in connection with the sag tables and curves for the National Electrical Safety Code.

In an Institute paper[2] which I think we may call one of the classics on this subject, Percy H. Thomas showed how, in plotting a curve between sag and stress, one could represent what we might call a generalized condition, by expressing sag as a percentage of span length and applying the loading in unit terms. That corresponds to the first formula of the paper and it is all right for the simple case which does not involve conditions of changing temperature, because it is changing temperatures that bring in the greatest difficulty.

A little later, two students, Messrs. Melvin and Wynne at the Massachusetts Institute of Technology, with whose thesis work I presume Prof. Dwight is not familiar, pointed out how a series of curves could be plotted to assist greatly in solving this problem. They plotted a whole family of curves which apply to different loadings of a given material, and then plotted on the same sheet of paper, another set of curves which are the stretch curves at different temperatures. The two families of curves intersect. (They used the parabolic relation in getting these but in the later work we have used the catenary relation in order to have them more accurate.)

What we call the stretch curve will represent conditions corresponding to some single temperature when the load on the wire is varied.

Now suppose the load is entirely removed from the wire; (and in that load I include the weight of the wire itself); we come all the way down on the stretch curve to the axis (the limiting member of the sag-stress curve being comprised of two axes)

1. A. I. E. E. JOURNAL, June, 1926, p. 564.
2. TRANS. A. I. E. E. 30, p. 229 (1911).

just as though the wire had no weight or load, and could be strung without sag or tension.

In using the old Thomas method, one would compute what we are now doing graphically; that is, take the load off the wire, get the condition of the wire with no load, then assume a change in temperature and find the change of the unstressed wire in length due to change of temperature. Upon arriving at that new length at the new temperature, apply the load again and then find the condition of the wire in sag and tension

The method of using the new charts is this: Pick out the point representing the stress,—that is, the tension reduced to pounds per square inch,—and the corresponding sag. You find what that is for your loaded condition.

Now then, if you want to find what the sag would be at some different temperature under the stringing condition of load,—that is, no load except the weight of the wire itself,—you follow the stretch curve to the axis.

The stretch curves are plotted for definite intervals of temperature, say, ten degrees. If the coefficient of expansion is a constant, it doesn't matter what the temperature is; one can shift the temperature scale to suit. Say you have taken the loaded condition at zero degrees and the stringing temperature at 60 deg.; you follow the axis for 60 deg. and return on another constant-temperature line to the load represented by, say, the weight of the conductor only. This point gives the stress and the sag for your stringing condition.

That gives a very rapid method of computing sags without any successive approximations and will fit any temperature and any loading. The only requirement necessary is that you have your chart to begin with.

If one has a great deal of this to do, it is worth while to compute the chart and have it on hand. Of course if one has only one problem to work out, it is easier to use the formulas. The author mentions a paper by Martin presented before the Engineers Society of Western Pennsylvania in which he has worked out some tables giving the catenary functions. They are very useful in a single case; in fact, we have sometimes found them preferable even in doing a lot of such work, since working over curves like these and attempting to interpolate between the drawn curves to obtain accurate results requires very close attention and careful work and it becomes very tiresome and exhausting if kept up for any length of time. On that score, it is easier to do computing, if you can do it, in a mechanical way with computing machines, as it takes a great deal less mental effort and less eye work.

I might say also that we have worked these charts out with the principal materials used, such as copper, aluminum and steel. In working them out, we used formulas somewhat similar to these in the paper, expressing the catenary functions in series.

H. B. Dwight: Has the work with curves for sag calculations, as described, been done for the case of supports at unequal heights or for cases of supports at equal heights only?

Mr. Lloyd: What I said applied to equal heights only.

H. B. Dwight: Is there any work on the other as yet?

Mr. Lloyd: No, not to work it out in the same way, except that with unequal heights, in considering the curve of the wire extended, you have always equivalent cases of equal heights of a span of greater length, of which your actual span is merely a portion; and you can always work it out in that way.

E. V. Pannell: The high degree of accuracy being striven for in transmission line-calculations is most noteworthy, but the question is whether the mathematicians have not gone a long way ahead of those responsible for testing the fundamental properties of material? While sag and tension calculations are being made to four, five, or even six significant figures, it must be admitted that knowledge of the physical properties of the wire does not come anywhere near this degree of exactitude.

The fundamental property in all calculations of wire extension is the modulus of elasticity. For copper wire, this is variously reported as from 16,000,000 to 18,000,000 lb. per sq. in. Here is evidently a difficulty and a possible error of 12½ per cent. In the case of aluminum, various investigators have reported a modulus of 9,000,000 and 9,500,000 and 10,000,000 lb. per sq. in., involving a possibility of error almost as great as for copper.

The properties of the wire when stranded into cables of various lengths of lay and characteristics become still more involved and except in the case of certain German laboratories, I know of no thorough tests having been made on a scientific basis by which attempt could be made to establish these properties.

It would seem as if the great degree of accuracy possible in a mathematical manipulation described by Dr. Dwight and other investigators is very nearly useless until the physical constants of wire and cable are more soundly established.

H. B. Dwight: The discussion by Mr. Pannell brings out a matter of considerable engineering importance. The physical characteristics of stranded cables, such as modulus of elasticity and temperature coefficient of expansion, are not known with exactness for standard conductors. Accordingly, further tests should be made to determine the average values of these constants and their usual amount of variation.

It is not necessarily obvious at first sight what is the effect of a certain percentage change in one of the constants, and it would appear to be a good engineering procedure to repeat a sag calculation using maximum and minimum values of a constant, so as to find what effect the variation has on the engineering decisions which depend on the calculation. If this were done for the two constants mentioned above, important changes in the results would be obtained.

In general, one should not write the values of engineering quantities with a precision greater by more than one significant figure than the precision of the measurements on which the quantities depend. Exceptions to this rule, however, are sometimes justified. For instance, one is justified in assuming the length of a span to be exact, as 800.00 feet. The sag calculation really deals with small changes in length. If the calculation should be repeated for a span of 801.00 feet the difference would be minute. If the length of span is considered to change after the application of a load, as by deflection of the towers, this should be taken up in a separate calculation.

When one wishes to compare two methods of calculation, one is justified in assuming for that purpose that all the constants are known with precision. The results are useful for the purpose intended.

Even where a constant is not definitely known, it is good engineering practise to adopt a standard value so as to design all the spans of a transmission line to have the same factor of safety rather than by irregular designing to have one span weaker than the others. Thus, a standard value of ice load or wind load is adopted even though the probable maximum value is uncertain. So also for the sake of uniform design of all the spans, it is proper to take a standard or average value of modulus of elasticity. The effect of possible variations in this constant can be made the subject of a separate investigation, as previously mentioned.

Where average values have been taken for several quantities, their deviations will probably cancel out to some extent in their effect on the final result, and so it is justifiable to carry out the computations based on the average values, with a moderate degree of precision.

The above mentioned reasons for making precise computations do not justify adding more than about one or two significant figures except in the case of the length of the span, or in the case of comparing two mathematical methods. In Table I of the paper by Dr. G. S. Smith[3], the modulus of elasticity is given as 29,000,000; that is, to two significant figures. This is multiplied by some quantities depending upon the section of the cable, and the result is given in section (13) of Table I as 3,153,306,102; that is, to 10 significant figures. This is due ap-

3. Transactions A. I. E. E., 1925, p. 938.

parently to the plan of writing the result of all multiplications with as many significant figures as a calculating machine will give, but when this is done, it does not seem possible to tell what figures have use and meaning and what have no meaning. Such a procedure masks the precision of the different parts of the calculation, and gives the impression that no attention is being paid to the relative precision of the calculation. It would seem better to give only such figures as are intended to be used.

The use of charts has a place in the calculation of sags, as described by Dr. M. G. Lloyd or as described in a number of A. I. E. E. papers. A chart method may give a sufficient degree of precision for a certain class of work, but this should be carefully determined. It should be remembered that a reading taken from a curve is correct to a certain number of significant figures, and the final result cannot be accurate to a greater degree than that determined by the curve reading. In sag calculations, especially where temperatures are involved, the discrepancies resulting from taking readings on curves may be greater than are desirable in designing.

The discrepancy between the values of deflections obtained in my paper and in that of reference (8) is due to the fact that two different catenaries have been assumed in the two papers, for the case of unequal supports with wind load. While the deflections are different, since they are measured to different lines, the difference in the stresses obtained by the two calculations is not appreciable for practical spans.

NOTES ON THE VIBRATION OF TRANSMISSION-LINE CONDUCTORS[1]

(VARNEY)

NIAGARA FALLS, N. Y., MAY 28, 1926

A. E. Knowlton: The principle of aerodynamics which Mr. Varney cites to account for the vibration of the transmission-line conductors is undoubtedly the same one which is found applied in the propulsion of Dr. Floettner's rotorship. The one difference is that he rotates the rotor and keeps the pressure always in one direction. That is not, of course, the case with the line conductors. The instability there results in alternation of the pressure and consequent vibration of the conductor.

Another and more important difference is that Dr. Floettner has made a useful application of it and one can't say as much in the case of the line conductors. The fact is that we get two distinct results; one useful and the other deleterious.

A committee of operating engineers is attempting to assemble the facts that have been observed and perhaps have been recorded in connection with this phenomenon, so that we can draw conclusions not merely as to the rigidity of the theory as Mr. Varney has set it up, but also upon the efficacy of certain preventive measures.

Theodore Varney: In closing, I think Prof. Knowlton's comment regarding Dr. Floettner's rotorship is appropriate. While Dr. Floettner turns the eddy effect of the wind to good account, the same influence accomplishes no good result in a transmission line conductor. It is not correct to say, however, that this effect is always deleterious in the latter case because cases are on record where vibration has been going for over ten years without interference in any respect to the continuous and successful operation of the line.

As the speaker views the matter, destructive effects will result from vibration only when the direct stress in the conductor increased by the stress due to vibration exceeds the endurance limit of the material of the conductor.

This is a complex problem, but it appears that the stress due to vibration is directly proportional to the stored energy in one half of each vibrating loop and inversely proportional to the distance over which that energy is dissipated. This energy is expressed by the mass of the half loop, the square of the amplitude and the square of the frequency of vibration. This energy passes back and forth freely between loops in the span away from the supports. At the supports there is an inevitable bump and increase of stress, which can be greatly reduced by care in clamp design.

The most beneficial remedy is to reduce the amplitude of vibration by dampers.

1. A. I. E. E. JOURNAL, October 1926, p. 953.

RECTIFIER VOLTAGE CONTROL[1]

(PRINCE)

NIAGARA FALLS, NEW YORK, MAY 27, 1926

R. H. Wheeler: The paper by Mr. Prince is a very interesting discussion of the potential possibilities of the use of the interphase transformer.

The interphase transformer has been utilized for a long time by Brown Boveri & Co., Ltd., and is incorporated in the circuit diagrams which the American Brown Boveri Electric Corporation has put forth in some of its proposals. We have not used the saturated-core type, however, for it long ago was demonstrated by many installations that the close regulation of the modern sets was sufficiently close for all traction purposes and very few industrial applications require the complications of the saturated interphase transformer.

Extended experience has also proved of late years that the compound rotary converter has not taken the position that it enjoyed some years ago when over-compounding was thought necessary. Wherever compounding is used of late it has been entirely of the flat compound type. To our knowledge, however, the shunt rotary converter has had a much greater application and appears to satisfy regulation and voltage conditions in all usual operations. To meet the flat compound or the over-compounded rotary converter, there has been introduced into the mercury-arc rectifier installation circuits an induction regulator which quickly compensates for the drooping characteristic of the rectifier and permits it to parallel at all loads with compound rotary converters.

There have been a number of schemes utilizing a variable-reactance core in the interphase transformer. The d-c., saturated core described by Mr. Prince has been utilized in a number of installations some years ago, but has since been abandoned because of a number of factors which limited the degree of compounding demanded by commercial practise. We have found that the rising voltage characteristic is not sought by purchasers of such conversion machinery.

The paper by Mr. Prince points out that the regulation is largely a function of the variation in load as it increases and decreases. The scheme as offered does not permit an independent voltage control. We have found that there are possibilities of utilizing shunt connections which will permit the movement of the voltage curves vertically upward or downward, at the same time obtaining the benefit of the control Mr. Prince has described. The Brown Boveri Review of 1919, Nos. 7, 8 and 9. describes such an installation and discusses the possibility of shifting the load by voltage control of the rectifier where a rectifier and rotary converter are operating in parallel.

During the extended development of the mercury-arc rectifier in large power sizes, as carried on by the Brown Boveri & Co. Ltd. of Switzerland, various schemes have been developed and patented, which permit of a flexible voltage control. These forms of control, however, include complications of circuits which demand additional reactance coils and machinery, and are not as commercially practicable as the circuits now offered, which provide for usual shunt characteristics. There is always available the induction regulator, transformer, tap changer, or similar device for changing the voltage of the sets.

The mercury-arc rectifier has been installed in heavy electric traction service at varying voltages up to 4000 volts, d-c. The limit of the phenomena of conversion by the mercury-arc rectifier

1. A. I. E. E. JOURNAL, July, 1926, p. 630.

does not seem to have been approached at the highest commercial d-c. voltages in operation today. The rectifier is causing a great deal of study to be made of its possibilities by engineers interested in the electrification of steam railroads, since the weights and dimensions are at a minimum not heretofore reached per kilowatt of substation output. No overhead cranes, heavy wall construction or heavy machine foundations are required in such substations. The operation of putting the machine in service or taking it out of service is no more complicated than throwing on the bank of transformers which serve the rectifiers, thus permitting the substation employee to be easily trained and of a type not essentially classed as "highly skilled." I can clearly visualize the use of the rectifier being established along the right-of-way of a steam railroad at much more frequent intervals than the rotating machinery type of substation providing much closer d-c. trolley regulation and obtaining alternating current from any commercial source of any commercial frequency, thus obviating the use of railroad-owned power stations and transmission systems.

It is interesting to note the control of the voltage and current curves as described in the paper by Mr. Prince. He sets forth the current characteristics in a very detailed fashion and we think that if it is possible to apply these schemes of voltage control to the twelve-phase rectifier, a very satisfactory current wave form will result.

Frequently we have been asked "What about radio interference?" because of the undulating character of the current wave form. Exhaustive tests were made by the largest utility company in the middle west, using very sensitive radio receivers which were moved about the substation, and placed in all positions, to determine the extent of interference with radio reception. The results of this test proved definitely that there is no interference caused by the wave form emanating from the rectifier and through the circuits it feeds. We believe this test is of interest, as the wave form of the theoretical circuit might cause an apprehension upon the part of some engineers if the practical test had not been made. Furthermore, full appreciation had not been given to the fact that the superimposition of many phases of rectification causes practically a flat wave rather than a sharply undulating wave.

Otto Naef: I think Mr. Wheeler is right when he says that in Europe not much use has been found for the interphase transformer with d-c. magnetization. The method proved successful from the point of view of voltage regulation, but this asset was not considered important enough to set aside the disadvantage of higher cost, lower efficiency and power factor in a plant thus equipped. Besides, there has been a marked tendency in Europe in the last few years to eliminate, so far as possible, any complicated features.

I may mention here that instead of using a saturated interphase transformer, saturated transformers or choke coils in the anode circuits may be used with equal success. In addition to, or instead of, a series winding, a d-c. shunt winding may be put on the core, which, if excited from the d-c. mains, makes it possible to raise and lower the characteristic of the rectifier in much the same way as in an ordinary shunt-wound, d-c. machine.

Mr. Prince's curve shows a very steep rise in the voltage at low loads, which is a characteristic feature of the interphase transformer. It can be avoided by using a booster transformer instead of the interphase transformer. It may be excited from the low side of the rectifier transformer through a reactance coil, the inductance of which is varied by the application of d-c. magnetization. In this way it is possible to vary the boost and thereby obtain compounding of the d-c. voltage without getting that first kick.

F. A. Fardon: Mr. Prince has removed one of the serious disadvantages of mercury-arc rectifiers when applied to railway service. A considerable proportion of the rectifier applications will be additions to systems where revolving apparatus having very definite characteristics is already in use. It is hardly conceivable that the characteristics of an existing system would be changed to permit the application of rectifiers with naturally drooping characteristics. On many occasions, it is necessary to install an additional unit in an existing station containing converters, and a rectifier with drooping characteristics would divide loads properly with the existing units at *only one* point. Beyond that, the converter would have a tendency to take too great a share of the load and at low loads the rectifier would cause reverse current to flow through the converter, which would at least force the converter off the bus and possibly cause other difficulties. This condition is analogous to attempting to operate a shunt-wound and a compound machine on the same bus, which we all realize is a very unsatisfactory arrangement.

It has been proposed that the rectifier be operated with converters where the regulation of the converter is poorer than that of the rectifier. This is a very unusual condition, and I am not familiar with any place where this condition exists.

With the method of compounding suggested by Mr. Prince, the interphase transformer may be arranged so that the saturating winding may be equalized with the series field of the converter, insuring load division at all points.

Compounding is desirable from an economic standpoint, as none of the features considered desirable in a rectifier are impaired and holding practically flat voltage at the substation is a condition which requires a minimum amount of feeder copper. This is applicable to approximately 90 per cent of the railway substations in this country.

A rectifier without compounding is comparable to a shunt-wound converter having about the same regulation, whereas, with the compounding feature, the regulation is practically the same as that of a compound-wound converter. Other methods, such as tap changing or use of an induction regulator, while applicable possibly to an isolated station, are objectionable on account of external devices requiring maintenance, and the fact that no induction regulator is fast enough to follow load swings on the average railway substation. If possible to build a regulator of this sensitivity, the maintenance would necessarily be high, as the unit would be in practically continuous operation.

The method of regulation offered by Mr. Prince is as simple as the series field on a converter. It will find large application and may be considered one of the most valuable additions to information on rectifier circuits made in recent years.

E. B. Shand: I more or less agree with Mr. Wheeler that the shunt-wound converter is becoming more popular now for traction and the value of the over-compounding or flat compounding is not as great as it used to be.

There is one point to be made, however. It will be noticed that with the core unsaturated you get the effect of the ordinary balance coil and that the anode current flows for one-third of a cycle, but that with the balance coil saturated it flows for only one-sixth of a cycle. That means the transformer will have to be about 25 per cent larger; so it will be economically at a disadvantage.

D. C. Prince: In the discussion of this paper, three questions have been raised: 1. Can the method be employed to give voltage control independent of line-current variations? 2. Is excessive transformer secondary heating introduced by the operation of compounding? 3. Will its popularity be reduced by the trend toward substation layouts which limit the load on one substation by dropping its voltage?

In answer to the first question, I should say that the problem of saturating the interphase transformer from a separate source is simpler than that of obtaining the correct characteristics by self saturation. If the latter problem is solved, the former follows automatically.

As a rectifier is loaded, the current waves in the several secondary windings spread out so that their utility factors improve. In a flat compound rectifier, the tendency of the compounding to make the utility factor worse is offset by the normal tendency of this factor to improve with load. The light-load utility

factors are three-phase 0.68, six-phase 0.55. The six-phase, short-circuit, secondary utility factor is 0.75 so that the transformer would not be expected to require materially greater secondary copper on account of compounding. Utility factor is defined as the ratio of no-load rectified voltage times rectified current to alternating sine-wave kv-a. for the same root-mean-square heating.

A very desirable thing about the compound characteristic is that by the use of high-reactance transformers it can be taken advantage of to hold substantially constant voltage to full load and yet with overloads the voltage breaks down more rapidly than that of a shunt machine so that the unit will shift its load to other substations. Since the rectifier cannot fall out of step, a generously designed set might be made to stand short circuit for a brief period without being tripped free of the lines.

LIGHTNING AND OTHER EXPERIENCES WITH 132-KV. STEEL TOWER TRANSMISSION LINES[1]

(SINDEBAND AND SPORN)

NIAGARA FALLS, N. Y., MAY 28, 1926

F. W. Peek: Messrs. Sindeband and Sporn's paper gives some very good data on practical lines in confirmation of experimental and theoretical work which I have been doing on this subject.

I have been very much interested as to the voltages that may occur on transmission lines due to lightning, the nature of these voltages and the ability of the insulation to withstand them. The spark-over voltage of an insulator is quite different for lightning voltages and 60-cycle voltages. Fortunately the lightning spark-over voltage is much higher than the 60-cycle, spark-over voltage and is not affected by dirt, rain, water or other foreign material on the insulator. About what voltages should be expected on a transmission line due to lightning and what is the insulator strength? If these factors are known it is easy to predict whether or not trouble is likely on any line. My investigation made partly in the field and partly in the laboratory on models with the lightning generator shows that the maximum voltage that can occur on a transmission line depends upon the height of the conductor above ground. In fact, the lightning voltage above ground on a line is equal to a constant times the height of the line in feet. Thus:

$$V = g\,\alpha\,H = G\,H$$

where H is the height of the line in feet, g is the gradient in volts per foot at the instant before discharge while α depends upon the rate of discharge of the cloud and the size of the cloud. It approaches unity for a large rapidly discharging cloud. The highest value of g is 100,000 volts per foot. The maximum voltage that can occur on a conductor insulated above ground is thus 100,000 times the height of the line in feet. For theoretical reasons it is easy to see that that value will apply only in case of a direct stroke. Since direct strokes are not a very common occurrence, data obtained on actual lines during flashover are of greater interest. Values of the apparent gradient of from 20,000 to 30,000 are quite common, while values of 50,000 have been observed.

The practical lesson that can be drawn from this formula, I think, is best illustrated by an example. I shall take height above ground and conductor separation approximately equal to Mr. Sindeband's case. Assume 40, 50 and 60 ft. as the average height of the conductors above ground. Assume further that the storm is about a quarter of a mile away and G is 25,000. The voltage on the top conductor is then $G\,H$ = 1,500,000 volts. On the next conductor down it is 1,250,000 volts and on the bottom conductor just 1,000,000 volts. If a 10-unit string of insulators is used the lightning spark-over voltage is 1,400,000.

For this particular storm and this particular insulator and tower the top insulator would spark over, while the middle and bottom ones would not. With a more severe storm the top and middle would spark over. At G = 35,000 all three insulators would spark over.

In confirmation, Mr. Sindeband's data show that most trouble occurs on the top conductor; next on the top and middle and finally on all three.

Incidentally, such data offer a method of measuring these voltages. If the top insulator sparks over and not the other two the voltage is known within the difference between 60 and 50 or about 20 per cent. From the voltage and height of conductor the gradient is known. If the top and middle insulators spark over, a similar measurement is made.

From the standpoint of lightning alone it is undesirable to have a high tower.

If the above conductors were placed in a horizontal plane 40 ft. high, the voltage above ground for this particular storm would be 1,000,000. There would be no potential difference between conductors as in the case of the vertical arrangement. For the storm in question there would be no spark-overs.

How about the ground wire? Theoretically and also from studies made on models in the laboratory a single ground wire approximately cuts the lightning voltages in half if it is installed under favorable conditions. If it is assumed that the above factor holds in practise it is equivalent, as far as lightning is concerned, to doubling the insulation of the line, but with one very decided advantage. Doubling the line insulation doubles the voltage on the apparatus while the ground wire cuts it in half. If it functions properly, there is thus a double gain in using the ground wire.

Whether or not there is trouble on a line from lightning is a matter of the height of the tower and the insulation and is entirely independent of the line voltage except as it governs the number of insulators and the height of the tower. Since high-voltage lines are better insulated, less trouble should be expected.

I wish to say a few words on Mr. Sindeband's work and experience. Arc-overs have been experienced first principally on the top insulator, then on the top and middle, and next on all three. Instead of putting a great many more insulator units on the line, Mr. Sindeband has installed ground wires hoping that the ground wires will materially reduce the voltages and thus reduce the trouble. In addition, he has added the device at the end of the insulator string, shown in Fig. 18. This device is known as a grading ring or shield and was first developed for 220,000-volt lines in California. Its object is, primarily, to make the voltage distribute evenly over the string and make each insulator take its share of the voltage. In this part of the country, where there are heavy lightning voltages, it causes them to divide evenly over the string and makes each insulator take its share of the voltage. However, another very important function of a device of this kind is in case of an arc-over. It seems impracticable to make most low and moderate voltage lines absolutely lightning-proof, though it can be done if the cost is justified by making the tower low, using a number of ground wires and extra insulators. It is very important, therefore, to have some device that will cause the arc to clear the string and prevent burning and cracking of the insulators until the arc is suppressed by sectionalizing or otherwise. A horn gap might be used for this purpose. Studies we have made with the horn, however, show that it is very difficult to make it effective. The reason is quite obvious. It is this: With the horn there is no appreciable grading; about 25 to 30 per cent of the voltage is on the line unit. The sudden application of a lightning voltage causes the bottom unit to arc over, then the next and so on up the string. A complete cascade results. Even though a horn is adjusted at 60 cycles to clear very well it does not clear when the arc is started by lightning unless the separation is greatly reduced. We have not found this to be the case with the ring; it causes an even distribution at the start and there is no tendency for the initial arc to cascade.

1. A. I. E. E. JOURNAL, July, 1926, p. 641.

It clears the string and the 60-cycle arc follows the path of the lightning arc. If the relays operate quickly there is no damage to the insulators.

There have been very few actual operating data on the value of the ground wire. However, recent work indicates that the ground wire functions as the laboratory experience and the theoretical work shows. You will observe in Messrs. Sindeband and Sporn's study, as would be expected, that most trouble occurred on the top conductor. In a similar tower equipped with a ground wire there would be practically the same voltage on all conductors. Data on a line with a ground wire should, therefore, show a more even distribution of trouble. That is exactly what has been found.

L. E. Imlay: We have one important tower line supporting six circuits on which we have five grounded guard wires. We have had no lightning disturbances on this line except in two instances when the lightning came in from connecting lines having two ground wires. From our experience we believe that five grounded wires on the top of these towers give practically complete protection.

L. C. Nicholson: The Niagara, Lockport & Ontario Power Company operates a system of some 2000 circuit miles, mostly at 60,000 volts with some 110,000-volt circuits. The practise of the company is to use ground wires. We have had experience both with and without ground wires. Our experience without them was very undesirable.

The construction that has gone up in the last ten years is of the A-frame suspension-structure type with square dead-end towers using two ground wires, the ground wires being used not only for electrical purposes but also, for mechanical reasons, to support the A-frame structures. The ground wires used are substantial in size and well grounded and have given little if any trouble.

While we can't say that flashover from lightning on lines equipped with ground wires is nil, yet it doesn't amount to a great deal. I think it would average, in rough figures, one flashover per summer per hundred miles on a double-circuit line. From five to seven insulator units are used on 66,000-volt lines. The 110,000-volt system is not very extensive and has not been in service very long so I am unable to give any conclusive figures on that.

The burning of conductors sufficiently to cause them to drop is almost unknown. I attribute this to the fact that the arc does not remain in one position long enough to burn the conductor in two or seriously damage it. I believe there have been occasions when small conductors dropped within a time period after the occurance, but the matter of burning of conductors is not a serious one.

Insulators do not puncture. This is another great measure of progress which has been made in the last 10 or 15 years. When we first started operating that was our main trouble. They now occasionally flashover, but are seldom destroyed or disabled.

E. S. Healy: There is one important phase of flashover trouble that should not be lost sight of. Under all reasonably possible wind conditions, adequate clearance must be maintained on every tower in a transmission line.

In rolling country, it is very easy to encounter special conditions that give short clearances. Any special construction requires a careful study.

Of course, any difficulties caused by insufficient clearance must be eliminated before a study of lightning effect can be made. In the two cases of flashover troubles that I have been entirely familiar with, inadequate clearance was at least a contributory cause. One of these was a tree which had probably caused occasional trouble for nearly two years before it was discovered. Aluminum and small copper conductors will blow out and carry the insulator into seemingly impossible positions.

S. S. Hertz: An entirely new engineering contribution in Institute papers has been made by the authors, and that is the analysis and publication of their *mechanical* experiences with overhead ground wires. Their contribution of field experience in its *electrical* aspect is also especially valuable, adding to the fund of data in several previous Institute papers on the electrical aspects of the overhead ground wire, such as those contributed by Dr. Steinmetz, Mr. Peek, Mr. Creighton and others. At the Midwinter Convention of 1922, Dr. Steinmetz strongly emphasized the electrical protective value of the overhead ground wire for certain types of lines, giving his preference to the overhead ground wire over the lightning arrester, principally because the advantage of the ground wire is that its function is preventive while that of the lightning arrester is merely curative.

Mechanically, the overhead ground wire has gradually undergone an evolution which is of value to note here. Starting years ago with barbed-wire and almost no standards of construction, the overhead ground wires have been gradually improved until today it is generally agreed that the overhead ground wire circuit should enjoy the benefits of the same standards of construction as are used in designing the power conductors. That is exactly what the authors have done in the lines described. Operating difficulties and troubles from mechanical failures of overhead ground wires which, on few properties, have prejudiced the use of any overhead ground wire, can be fully solved by improving construction standards. The overhead ground wire, if used at all, should rigidly adhere to at least the same standards of material and construction as used in designing the power conductors with which they are to be placed.

The following improvements in construction standards are the ones which appear most needed to bring the trend of overhead ground wire design to par with the general design of power conductors. These standards have been employed on several of the recently constructed transmission lines:

a. Use of suspension clamps and strain clamps for the ground wire of the same general design as used for the power conductors.

b. Placing slightly less sag in the ground wire than in the power conductors (in sleet districts). This is advisable to provide ample separation when the ground wire is carrying sleet while the power conductors have shed their sleet load.

c. Use of non-rusting wires, so that the natural life of the ground wire will be at least that of the power conductors.

d. Assigning a slightly greater factor of safety to the ground wire than is given to the power conductors. For example, where the power conductors are designed with a safety factor of 2, it may be advisable to have a factor of safety of about 2,25 in the ground wire. In emergencies affecting the supporting structures, the ground wire would have to bear the greater part of the strain and in any occurrence of trouble it is good practise to have the ground wire safer than the power conductors.

H. B. Vincent: I'd like to ask Mr. Sindeband two questions: Has he determined the most efficient setting of the arcing ring with respect to the wet flashover of the string? In other words, what percentage of the wet flashover of the insulators is the wet flashover of the arcing ring? If so, at what ohmage water is the wet string figured?

Has he any record of troubles which actually occurred during rain storms?

Is the flashover shown in Fig. 18 a wet or a dry flashover?

N. J. Neall: Something that has been said in the discussion prompts me to mention a feature of lightning-arrester performance that has been observed during the last year in connection with some comparative tests of lightning arresters on an 11,000-volt system where a number of circuits are carried in a parallel horizontal plane arrangement to a given substation over an H-frame construction. It was found that the arresters attached to the upper transmission wires, particularly those just under the overhead ground wires, were the principal ones to discharge and the inference, pending further information, is that we have a sort of succession of protective zones beginning with the over-

head ground wire and then downward from conductor plane to conductor plane.

A. O. Austin: With the rapid changes in transmission work, there is a tendency to make an installation which is copied in many instances before operating records are available which will show up difficulties or advisable improvements or modifications. Hundreds and even thousands of miles are put in before any real operating experience can be obtained. This time lag is unfortunate and leads to a serious situation because line trouble of any description affects not only the operation and subsequent expenditures but financing as well.

In 1916 I presented a paper before the Toronto Branch calling attention to the dangers which were likely to occur with an increase in the size of the system, unless the factors of safety were materially improved. The discussion today brings this out clearly, hence the extended interconnection of large networks should be given careful attention as the increased trouble frequently more than offsets any economic advantage. The splitting up of systems, during storm periods or where the margin of safety is rather small or the circuit breakers likely to blow up, should also have more attention. A short circuit on the line today is far more serious than it was a few years ago owing to the fact that conductors are generally larger and the amount of current fed into a short circuit will create far more damage, not only to the line but to the possible connected apparatus. The time of clearing a short circuit also tends to increase with the size of the system in order to obtain selective relay operation.

Today plants are penalized for poor power factor, which results in loading the motors more heavily so that a drop in voltage frequently allows much apparatus to drop out of step. This causes heavy losses in some plants and inconvenience in all, warranting considerable expense where even momentary drops in voltage or bumps on the system can be eliminated.

In addition to the increase in number and seriousness of transmission interruptions, the cost of transmission lines is becoming more of a factor in the total cost of power. Additional parallel circuits are required to offset interruptions where lines are subject to flashover. The additional cost must be incurred whether or not the line can be cleared with a relay and circuit breaker. On some of the large systems considerable time is required following what would normally be considered a momentary interruption on a small system, before the line can be put back into service. There can be little question but that the success of future transmission systems demands that flashovers be eliminated as any other method is too costly and uncertain of results.

The whole subject needs the most careful consideration. If we apply common sense and carry the analysis far enough it will be found that there is general agreement as to the fundamentals necessary for the construction and operation of a transmission system. Above all we should not expect results which are not justified either partially or wholly by consideration of fundamentals.

The ground wire is a good example in point. A poorly installed ground wire may cause much mechanical trouble and while it may be of some benefit in reducing induced voltage or in absorbing a surge, the trouble which it causes may more than offset any advantage. Where the ground wire is installed on a wood pole it may so reduce the insulation that flashovers will result even though the maximum voltage may be reduced. While the shattering or burning of poles may be prevented, the increase in bird troubles and the elimination of the insulation furnished by the wood may more than offset any advantage in the use of a ground wire in this case.

Where a ground wire is installed on a steel structure the situation is somewhat different since there is no insulation in the structure to cut out. If the ground wire has good mechanical reliability it will, of course, reduce the maximum voltage tending to flash the line and, in general, conditions will be improved. There are some cases where the ground resistance is exceedingly high and if this resistance is materially reduced by the use of a ground wire, short circuits from lightning and birds will be increased.

An analysis of the field conditions, as well as tests in the laboratory, shows that a very great improvement may be expected from the complete impregnation of poles which will eliminate a low-resistance core. This low-resistance core tends to cause the pole to be shattered under lightning. This shattering can be eliminated only by increasing its resistance or by providing a shunt path. The former may prove most economical for new lines whereas the latter may be necessary for lines already installed. A down lead or lightning rod on the side, while saving the pole, tends to eliminate the insulation unless the ground resistance is high. In some cases the use of a gap in this circuit may be used to advantage in increasing the effective insulation for a surge or to prevent bird or squirrel trouble.

In the construction of a new system better operating conditions will be obtained if the cost of a good ground wire is used to provide more insulation and tower clearance or a more favorable electrostatic field around the conductor or live parts in the vicinity of the tower.

The old method of using a compass in tower design to determine clearance should be abandoned, as two towers having the same clearance may set up widely different electrostatic-field conditions so that one tower may have many flashovers while another tower having the same clearance may have few, if any, under the same conditions.

The ground wire is an old device and outside of improving its mechanical reliability, its application has developed little, if any, over a number of years. Practically the only improvement has been the limited use of the insulated ground wire which has given very good results.

It would seem that an improved application of the ground wire is very necessary and desirable if we wish to improve its effectiveness, and it is predicted that a great increase in its efficiency will be possible in a short time.

Bird trouble is a serious problem on some systems but it may be readily eliminated if wood poles can be kept from shattering or burning. This subject is receiving careful attention and reports from the field as well as experimental results would indicate that material improvements are possible in this direction. I am certainly not against the use of a ground wire. If, however, we find an improved method of using it or increasing its efficiency we may do much to reduce trouble and the cost of transmission lines.

The discussion today apparently leans toward the low structure. While I do not believe that this is essential where the necessary factor of safety is provided to offset the greater voltage induced on the line, it has certain advantages. The low structure means more supports and more insulators. More supports will permit the use of lighter insulators with much longer economic life which more than offsets the increased quantity. Where the low structure with its lighter mechanical loads is used it is possible to provide towers or structures which will set up a more favorable electrostatic field and thereby provide a higher flashover voltage between conductor and ground for a given length of insulator.

Owing to the fact that the electrical problems in preventing flashover on the transmission line are not so generally understood as the mechanical problems, there is a tendency to develop the mechanical end of the structures at the expense of the electrical performance of the line.

Unless the ground wire is so situated that an effective shielding exists, the upper conductor receives the greatest stress. While this is generally recognized there are few lines which provide more clearance and insulation for this conductor. On the contrary, the upper conductor usually has the lowest flashover stress for operating conditions. This results in much more

trouble than would be the case were the insulation and clearance graded in proportion to the stress imposed, whether this be the top conductor or the lower conductor. If the location of the ground wire reduces the stress on the top conductors so that the lower conductors have a higher maximum induced voltage we should provide greater insulation and clearance for the lower conductors. An arc from conductor or live surface to a tower member or ground is bound to be destructive if there is any appreciable power connected to the system and the successful line of the future will be designed to prevent arcs to ground rather than minimize their damage after they form.

In some cases it is necessary to minimize the destructive effect of flashovers, as it may not be possible to eliminate flashovers without incurring a prohibitive cost. The success, however, of some rather low-cost lines leads us to believe that a great improvement may be possible through a proper consideration of tower design and clearance and a better realization and use of the ground wire itself.

While the ground wire has been improved mechanically, its electrical efficiency has not been improved over the earlier installations. In some cases I have used a ground wire effectively to eliminate troubles which were very serious. In others trouble has been materially reduced by the removal of the ground wire. Hence, its economic importance depends upon the particular application.

More attention must be given to the tower as many of the newer and more expensive lines have made a poorer electrical showing than some of the earlier and cheaper lines. This is natural in a way as building costs have gone up tremendously and the tendency has been to offset the increased cost by building towers of smaller clearance or greater mechanical strength to handle the larger conductors. Since fixed charges form an appreciable part of the cost of power on many systems we are likely to use designs which cut the factor of safety, causing increased troubles, particularly where there is no precedent upon which to draw. There is a tendency to use a relatively shorter arm with the increasing size of conductor. This, together with the high braces and wide face of the tower in the direction of the line, while economical from the tower standpoint, makes the problem of preventing flashovers exceedingly difficult. Tower clearances in the past have been laid out by means of a compass rather than by studying the electrical field set up.

Much time and thought has been given to this subject over a period of years and I feel that within the next year a material improvement will result in the construction of transmission lines as the relative performance of different constructions can be determined experimentally to a very large extent and it is gratifying to know that results in the field apparently conform to tests in the laboratory.

It is exceedingly difficult to improve the standard of an existing system although it is evident that if a system having a low standard of operation is connected to another portion having a high standard, both of them will operate on the lower standard. Usually anything within reason which will raise the standard of the old system is justifiable and much time has been spent upon this problem.

It would seem that a new system should go in with ample clearance. I should rather see a new line go in with ample clearance and no ground wire rather than have the system installed with a smaller clearance and an expensive ground wire, as the latter can always be installed later whereas increasing the clearance after installation is a difficult and costly proceeding. Owing to the more severe conditions which may arise through interconnection, a ground wire which was unnecessary on the smaller system may prove advisable and can be installed at little additional expense over that necessary were it incorporated in the first installation.

As systems grow the demand and value of greater reliability increases and if this is hampered by too small a clearance or poor field conditions at the tower, the problem of providing greater reliability will be exceedingly difficult. While certain fundamentals are recognized clearly in the laboratory, it seems to me more difficult to recognize the application of the same fundamentals in preventing flashover on the transmission line.

On the transmission line the problem is to prevent an electrical discharge between the conductor or live part and the tower and support. The problem is to prevent the break-down of the air; hence, anything which will affect the maximum stress on surfaces which will normally discharge will have an effect upon the flashover voltage. It is obvious that the density of the field surrounding a conductor or a live part may necessarily vary greatly for a given clearance with the wide range in tower designs so that general statements based upon a specific instance may be very misleading. In most lines the discharge starts probably from the conductor or live part while in others there is reason to believe that the discharge actually starts from the tower or ground side owing to the fact that the greater density in the air is produced on this side of the gap. Where the latter condition exists, increasing the size of the charged surface on the conductor will necessarily tend to lower the flashover voltage and increase troubles, although in other cases this might be a very material advantage. While this is too large a subject to go into detail, a consideration of the conditions between electrodes will illustrate the problem fairly well and not only show the inconsistencies but, what is even more important, a means for increasing the flashover voltage for a given clearance. While this is fairly simple between ordinary electrodes, the problem is more difficult in service owing to the effect of rain and mechanical considerations.

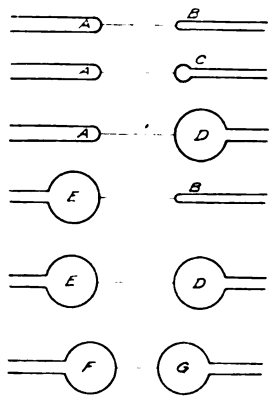

Fig. 1

Referring to Fig. 1, if we have a grounded electrode, A, and a live part, B, with a given distance between them, it is comparatively easy to determine their flashover voltage for conditions which are likely to exist on the line. If we maintain the same clearance between electrodes but use electrode C in place of B, the flashover voltage under the same conditions will be increased, particularly if we pay no attention to polarity. If, on the other hand, A remains the same and we replace the electrode C by electrode D, the flashover voltage will be reduced and may be even lower than that for A and B, owing to the greater concentration of stress in the air around electrode A. If we replace electrode A by electrode E on the ground side in combination A-B as in E-B, the flashover voltage may still be the same as in the previous case A-D, but will be lower than for A-B. If E represents the electrode on the ground side, and D on the line side, the flashover voltage will be materially increased over any of the previous cases. There can be no question about this and it only remains to make the application to the transmission line in order to improve the flashover voltage materially with the

resulting decrease in the number of flashovers. Up to the present time, there has been no line application which corresponds to the gap *E-D*, the applications being more on the basis of *A-C* which must necessarily have limitations compared to the possibilities of the gap *E-D*. There is one other case which it is well to consider, and that is the condition where we have a gap similar to *F-G*. In this case, while the electrodes apparently give a better field, their projection into the field or reduction in clearance reduces the flashover voltage until it is as low if not in some cases lower than the normal gap *A-B*. When we can make use of a dielectric which has a greater strength than air, together with some of the favorable conditions above outlined, it is possible to raise the flashover even for a given clearance far above anything now in use. Air gradient and not string gradient is the real problem.

There are three general schemes which may be used to advantage in connection with steel towers. One is to increase the clearance and improve the field conditions as discussed above. The second is to lower the maximum induced voltage by the use of a ground wire or lower the height of the structure. The third is to control the field in the vicinity of the conductor or at the upper end of the string so that the maximum flashover may be developed for any stress which may exist in operation. This is readily solved by the use of a sphere-gap in the laboratory and it may be approximated for transmission work. In the case of wood supporting structures the problem may be somewhat different as most wood structures furnish insulation which will provide a higher flashover voltage than exists on the largest steel tower line now in operation. The problem in this instance then is to make use of this insulation and increase the life of the structure. Complete impregnation apparently reduces the tendency to shatter and at the same time increases the life. In some cases it is further necessary to prevent burning due to leakage or due to discharge and experimental results would indicate that great improvement in this direction will be available shortly.

In the case of the steel tower, the economic problem is to develop the break-down strength of the air path and in the case of the wood structure to prevent burning or shattering. Much time has been spent on this over a period of years and possibilities in these directions are far greater and more nearly at hand than generally supposed. In many cases it may be advisable to effect a compromise of the several means to get the best economic results. It goes without saying, however, that improved flashover voltage over existing lines must be provided for the large system if high-powered transmission networks are to be extended much further. It seems that this problem together with the use of a lower transmission frequency are the most important ones facing the long high-powered line of the future.

J. H. Cox: Among engineers there seems to be a tendency to question the theory of a phenomenon and to question substantiating laboratory data until the case is proved by actual experience in the field. The theory of the ground wire has long been known. With typical arrangements, this theory indicates that by the use of a ground wire, surge voltages induced by lightning are reduced from about 40 per cent on the top wire to about 25 per cent on the bottom conductor, with vertical configuration. Mr. Peek's work with his lightning generator indicates a still greater protection, or about 50 per cent. Finally, these field experiences of Messrs. Sindeband and Sporn should establish beyond question the usefulness of the ground wire.

It seems strange, with theory indicating as it did a large measure of protection, that when trouble was encountered due to mechanical reasons the obvious solution—that of better mechanical installations—was not practised.

The proper proportion between line insulation and apparatus insulation has received too little consideration in the past. The authors bring up this point. Obviously it is less serious to have a line flashover than a bushing flashover or insulation puncture. During the past two years the Westinghouse Company together with the operating companies, has conducted surge investigations with the klydonograph on a great many power systems. During these investigations, we have conducted tests on 66-kv. lines having line insulation ranging from pin type, or three 10-in. disks to ten 10-in. disks. In spite of the ground wire, we shall always encounter a certain number of flashovers due to direct strokes and the highest induced strokes. More attention should be given this matter so that apparatus is not subjected to these higher potentials by over-insulating the line. On the other hand too low a value of insulation permits an excessive number of flashovers at a voltage lower than necessary and too low to permit the operation of lightning arresters.

There is a point in this question which though evident might bear mentioning. The proportional protection from flashovers afforded by a ground wire is far greater than that indicated by the reduction in surge voltages. If the number of surges between various voltages over a long period are plotted against voltage and a curve drawn through the points a curve is obtained resembling a probability curve as shown in Fig. 2.

If the full line represents the number of surges of various voltages on a particular line without a ground wire, a curve of the surges encountered on the same line with a ground wire

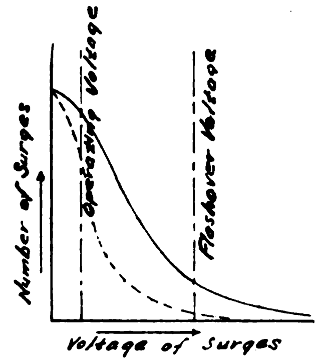

Fig. 2

would be displaced by the amount of the reduction accomplished by the ground wire, giving the dotted line. A vertical line may be drawn at the impluse-flashover voltage of the line in question. The flashovers of the line are caused only by the surges lying to the right of this vertical line. It is clearly seen that the flashover region under the dotted line is less than the flashover region under the full line by more than the percentage reduction.

Our tests with the klydonograph checks the authors' experience in that the highest potentials from lightning were always on the highest conductor and the lowest on the bottom conductor.

There were two points brought out in the discussion towards which I might be able to contribute. The question was asked as to whether flashovers were encountered at some distance from the lightning stroke, indicating a higher potential at some distance from the source. In our experience with the klydonograph, we have never encountered this situation except in the case of a flashover on an isolated-neutral system. We have encountered surges of the order of one million volts and at a distance of 50 mi. no potential greater than normal line potential was recorded. Where the lightning caused a flashover on an isolated-neutral line an over-voltage would be recorded at all stations no matter how long the line. This, however, was due to the acting ground set up by the flashover.

Another question brought up was whether or not the upper conductors afforded protection to the conductors beneath them. From the theory of the ground wire this is not possible except where the upper conductors flashover. The only protection afforded by the ground wire is due to the fact that its charge dissipates to ground with the discharge of the cloud and the

presence of a conductor remaining at ground potential reduces the potential induced on the neighboring conductors. The only way in which the upper conductors could shield the lower conductors is by discharging their charge to ground either by means of the flashover or by lightning arresters.

V. Karapetoff: In considering the influence of the ground wire, it is necessary to distinguish between its effect in reducing the over-voltage and the over-charge. These two effects are expressed numerically by different ratios. Consider the simplest case of a single conductor without any ground wire, with a cloud above charged positively. Then you have a negative bound charge on the wire, with the positive charge conducted to the ground through leakage. When a lightning flash takes place, the bound charge becomes free, so that the protective equipment is subjected, first of all, to an over-voltage, and secondly, there is a definite bound charge which has to be conducted to the ground, say, through a lightning arrestor.

Now consider a ground wire near the conductor. Certain equations may be established for the bound charge, etc. A solution of these equations gives the over-potential to which the line wire is subjected immediately after the stroke of lightning, and also the value of the charge released on this wire as a result of this stroke. The new values of over-voltage and of released charge may be compared with those obtained before, without the ground wire.

As a result of some computations which I have had an opportunity of performing lately, I find the ratio of the two over-voltages to be somewhat different from that of the two charges. Depending upon what you are interested in, that is, whether it is the maximum instantaneous over-voltage or the discharge capacity of the protective equipment (which is bound with the magnitude of the charge and not of the voltage), your judgment about the protective value of the ground wire will be different. My computations, unfortunately, have been made only for this simple combination. It would be desirable to continue these computations so as to include, say, three or six line conductors and a ground wire.

Herman Halperin: In my work as chairman of the A. I. E. E. Subcommittee on Lightning Arresters during the past year, it appeared that the members of the subcommittee and other engineers had many opinions as to the means of coping with lightning disturbances on high-voltage lines, especially those operating between 66 kv. and 154 kv.; but there were little definite data of operating experience, which is the final criterion, to show just what was accomplished by certain types of protection or methods of diminishing the magnitude of lightning voltages. The subcommittee members felt that more operating companies should gather complete data regarding the lightning on their lines, analyze the data, and submit papers along the lines of the one submitted by the authors today. Their paper is especially timely, as it concerns a voltage on which there is considerable discussion. I am sure that the industry will look forward to another paper in two years to compare the coming two years' experience of the authors with ground wires with the last two years, when ground wires were not used on certain lines.

In the future investigations of the authors, it might be well to obtain some data as to the magnitude of transient voltages on their lines, by means of a recording device such as the klydonograph. These data, when correlated with the operating experiences, will give a more definite idea of the effectiveness of the various designs in coping with lightning on their lines.

M. L. Sindeband: Mr. Cox mentioned the problem of insulation. In this paper, we mentioned the matter of over-insulating the transmission line and the bad effect this would have on the equipment in the substations resulting, as it would, in pushing the high voltage from the line into the stations. Of course, the ground wire would leave the transmission-line insulation unchanged but by cutting down the induced voltage it would have a particularly beneficial effect on the substation equipment since, as a general rule, the oil switches and transformers are not insulated as highly as the transmission line.

When we first started this problem and considered the idea of adding more insulators, the manufacturers of equipment objected since they argued that if the insulation of the line is going to be boosted, the insulation of the equipment should be boosted at the same time and they were afraid that this would lead to large expense. If that were done,—that is, if the line insulation were raised,—it does not necessarily mean that the equipment insulation has to be raised likewise since the station and substation equipment has, as a general rule, the benefit of a lightning arrester but the moment you go into that you enter into another controversy—namely, the lightning arrester—and there is almost as much disagreement about that as there is about the ground wire.

Mr. Vincent asked what particular feature of the rings governed their design. We experimented with the design of the rings only in so far as the clearing of lightning flashovers and 60-cycle flashovers were concerned. The wet proposition was not considered at all.

Now as to the table listing the troubles: On our original table sent in to the Institute we had some marks indicating which were under rain conditions and which under purely lightning conditions. Unfortunately, they were left out in printing. However, as we recall it, practically all of these troubles occured during rain periods, that is, they were a combination of rain and lightning.

Fig. 18 is a 60-cycle dry flashover test.

In conclusion, I wish to state that I believe that the operating companies should contribute their bit in helping the manufacturers of equipment with this problem, because certainly the manufacturing companies do spend a great deal of time and money for this purpose.

AUTOMATIC AND SUPERVISORY CONTROL OF HYDROELECTRIC STATIONS

(Smith)

Niagara Falls, N. Y., May 28, 1926

W. H. Gerrie: It may be of interest to relate some operating experiences in connection with two such plants as Mr. Smith has described. The plants I refer to are on the Central Ontario System of the Hydro-Electric Power Commission and consist of three generators per plant, the capacity of the units in the one being 2000 kv-a. and in the other 1400 kv-a. Excitation is supplied by direct-connected exciters and control by one regulator of the vibrating type in each plant. The plants are located on a navigable stream, the levels of which are required to be maintained within very close limits. Both plants are controlled from one point and the operator in charge has to operate in addition the plant where he is located, which has a capacity of 9000 kv-a.

The following satisfactory points have been observed up to the present:

(1) The reliability of the sequence relays.

(2) The saving in time of bringing on generators by the self-synchronizing method.

(3) The apparent reliability of the supervisory equipment.

In connection with the second point it is interesting to note that we are obtaining satisfactory results with the self-synchronizing method on generators that are not equipped with damper windings, but which have solid field poles. This is in part contradictory to the statement contained in Mr. Smith's paper.

Our experience so far has shown that we have had more troubles due to dirty contacts and sticking supervisory relays than we have had with the sequence relays. While their operation has given a fair degree of satisfaction, the troubles we have experienced point to the necessity of having a specially trained man available to analyze and eliminate these troubles with the least possible delay.

Some of the points on which we are rather skeptical at present are as follows:

(1) The economy of this system of control where less than four plants are so operated in the same territory.

(2) Whether the governors will perform satisfactorily enough to insure reliable operation after they have been in service for several years.

(3) Whether the method of controlling excitation by one regulator should be encouraged where several direct-connected exciters in the one plant are used.

(4) The proper method of obtaining battery-charging supply.

(5) Whether the remote meters as they at present exist are sufficiently reliable for satisfactory operation and for system operating records.

Elaborating on these, I might say that it is desirable to have an attendant available at each plant for ordinary cleaning who can be called out in cases of emergency. Also it is desirable to have a specially trained man for ordinary inspection who, in case of trouble on the supervisory or sequence relays, can locate and remove the trouble with the least possible delay. Under normal conditions this man should be able to handle four or five plants. Where only one or two plants are in service, the cost of his time together with the carrying charges on the additional capital cost of the plants does not leave sufficient margin to say definitely that the remote-control plant is justifiable. The same is true of the governors. These devices should have expert inspection and adjustment and this is not always available on small systems.

We have had considerable difficulty in obtaining balanced reactive loads with balanced kw. loads between generators in the one plant. This may become serious enough when operating at full kw. load to introduce excessive heating, causing the generator to be tripped off by thermal protection when it can least be spared. This trouble is directly attributable to the regulator operating under the above mentioned condition.

We have in use at these plants two systems for obtaining battery-charging supply, *viz:* (1) from the exciter system, and (2) from rectifiers. The first is impractical in that it cannot follow the ordinary system voltage variations between day and night conditions and between week-day and week-end conditions. The latter difficulty is particularly aggravated where a holiday follows a week-end. Also there is considerable inconvenience from blowing fuses on high excitation which, when it occurs, causes the battery to go on discharge. The rectifier has not as yet proved that it is reliable. It would appear that the most satisfactory results should be obtained from the motor-generator charger.

Two methods of remote metering in use are (1) current method and (2) impulse (condenser) method. While the latter method has given fair results, it is not without certain inherent defects the most serious of which is that variable control voltage will change the calibration. The time lag to the meter also is not a desirable feature when adjusting load on the plant. Extreme warm weather also affects the viscosity of the damping fluid to such an extent as to give an entirely different chart, although the actual frequency regulation may be the same. Also some of the condensers have become defective. Indications so far point to the current method as being the most satisfactory that we have experienced.

The operating company must thoroughly appreciate the manufacturer's difficulties in development in a new art such as this and be willing to cooperate in supplying operating data so that faulty applications may be weeded out. The manufacturer on the other hand must fully appreciate his responsibility in the development of a new art and wrong applications must not be permitted to get out into the field.

Another point that should be emphasized is the necessity for competent centralized supervision of such installations. The whole work should be under the supervision of a competent field engineer who is able to correlate all sections of the work.

It is also very important that manufacturers make a thorough analysis of system operating conditions before proceeding with any installation and the operating companies should lend all assistance possible in supplying the necessary operating data.

In Mr. Smith's paper I note that in section (G) he refers to shutting a unit down when the voltage drops to 80 per cent of normal for several seconds. In actual practise this works out as unnecessary protection and we may find the system dropping load on ordinary system surges.

Reference is also made to the use of annunciators for bringing to the attention of the attendant troubles of a serious nature. It cannot be emphasized too strongly that these annunciators should be very reliable. Also it has been my experience that the tendency is to have an insufficient supply of them.

Mr. Smith says that the multiple-unit station gives rise to no particular problem. I would like to draw attention, however, to the complications of such a system. It seems to me that the division of excitation is a real problem. Mr. Smith refers to one installation for the New England Power Company using direct-connected exciters and separate regulators. A description of the method of voltage control, in the light of the difficulties that I have already mentioned in using the one regulator, would be of interest.

Mr. Smith refers to the fact that in general the direct-connected exciter is by far the more desirable for automatic control. It might be of interest if Mr. Smith would elaborate on the various reasons for this statement. Also in applying this system of control to old stations which generally have the motor driven and turbine driven exciter, it might be of interest to know whether any problems of a particular nature would be introduced. It seems to me that the question of excitation unbalance between generators referred to above would be entirely eliminated with the one exciter, but it may be that other complications are introduced which make the direct-connected exciter preferable for automatic stations.

C. F. Publow: I would appreciate having Mr. Smith give details regarding the following functions which he notes automatic equipment is generally arranged for.

(1) Item "D": Protection against motoring the generator. We have found that owing to the changes in system frequency between the time a unit is shut down and started again, although of a very small order as will be shown later, yet when a unit is brought on it occasionally closes its gate tight and motors on the line until such time as the operator discovers the situation and corrects it. This in many instances would take upwards of at least a minute and I am interested in knowing what form of protection has been found suitable for such cases, as I believe this performance will be common to any system and more especially to some of the ones Mr. Smith refers to where the frequency varies upwards of five per cent.

(2) Item "F": Charging the battery. I would be interested to have Mr. Smith state definitely what method of battery charging he refers to. We have two methods (from rectifiers and from exciters where vibrating type regulators are used) neither of which has proved satisfactory.

I note Mr. Smith refers to using the exciter voltage for operating a speed device for placing a unit in service at approximately synchronous speed. How closely can this method be depended on to repeat itself? It would appear to have the disadvantage of having no protection for high exciter voltage, which would occur on overspeeds.

I was particularly interested in Mr. Smith's description of the connections used in mounting the protective equipment for the supervisory connections between stations, and I would appreciate a statement as to the functions of the various parts of this protection.

I would appreciate getting an expression of opinion on the following:

(1) The desirability of grounding the positive terminal of the

battery which supplies power to the automatic telephone type of supervisory equipment.

(2) The use of oil dash pots for controlling the governor during the initial starting period. This type of control has the disadvantage of (a) permitting "creeping" and (b) variations in its performance due to temperature changes.

In this connection I would like to ask if a motor connected to the governor stop control lever has ever been used. It appears to me that this device could readily be adapted for this work and overcome the two disadvantages noted above in an oil dash-pot control.

(3) The most desirable source of energy for the motor-driven governor fly-ball. Use has been made of potential transformers on the two stations on the Commission's system, but this supply is of no use in event of a machine pulling out of step. Slip rings connected to the exciter and mounted above the commutator would seem an ideal source of power supply for this important service if it can be obtained at a nominal cost.

(4) What would be considered a satisfactory value in ohms of a station ground in an average hydroelectric station, where remote supervisory installations are applicable.

Remote supervisory control to be successful is dependent on:

1. Reliable control circuits connecting the control and remote stations. These should remain intact except in cases of direct lightning strokes or where a high-voltage line falls on them and in such instances the protective equipment should function to limit the damage done to the point where the fault occurred.

2. A signal once started by the operator at the control point or automatically by the equipment at the remote station must repeat itself until the "answer back" or equivalent is received which de-energizes the repeating circuit; *i. e.*, indications must be correct, or by repetition warn the operator that trouble exists, and the design of the equipment should incorporate the feature that the equipment at the two ends will re-synchronize before repeating the code.

3. The equipment in its design must incorporate No. 2 above and be mechanically rugged enough to perform the service required of it with a minimum of maintenance.

4. Means should be provided which will permit canceling a supervisory signal where one has been put through and the automatic sequence has failed to complete its function at the remote stations. Under such circumstances the operator may be helpless and considerable damage may result before an attendant can be rushed to the remote station. This feature seems desirable in addition to the automatic sequence scheme being arranged to permit only one start, in event of trouble, unless the supervisory signal is repeated.

5. When there is a considerable number of indications, some are much more essential than others and it may be desirable to have incorporated in the supervisory scheme, means of giving these more essential signals precedence over the other. In all cases I believe it would be advisable to give order signals from the control station precedence over signals originating from the remote stations.

6. A high degree of maintenance care. This should be generally in one individual's charge who is fully familiar with the circuits and the operation of the equipment.

Automatic switching equipment can be made thoroughly reliable by adhering to the following points:

1. That the sequence scheme is well adapted for the work it must perform.

2. That suitable relays and corresponding equipment have been chosen which will always perform their function accurately whenever required and failing this will make the sequence inoperative.

3. That a proper assembly of this equipment has been carried out. This applies to their location and connecting with a view to their particular function from a safety standpoint and also with ease of maintenance. It would seem desirable that all contactors should be provided with positive wiping contacts which will assure good contact even though they are dirty.

4. That the equipment should be carefully adjusted by thoroughly competent men when installed, to perform their particular function so accurately that they may be depended on to "repeat" and that for the first few months this performance be carefully checked and an accurate record of it kept. This record will serve as a guide to the frequency of inspection required in the various parts later on. The speed device is an exceptionally important one to which the foregoing comment is particularly applicable.

5. Workmanship of a high order is required on the various devices used and in their assembly.

6. A competent maintenance man should be in charge of the equipment. It is essential in maintenance work to be observant of equipment the functioning of which will inherently vary with weather conditions, and in this connection I believe manufacturers should supply data on the performance of their equipment of this nature. This will materially assist the operating companies in making the needed adjustments and in this way they will be warned of the necessity of watching these points carefully. The dash-pot control of the governor for controlling the unit during the starting period is a good example of this type of device.

In the installation and initial operation of both supervisory and automatic equipment, too much care cannot be taken in accurately checking, point by point, every piece of equipment.

The following points should be given attention:

(1) Careful consideration should be given to the mechanical work where devices are attached to the generators in order to avoid their being damaged during disturbances.

(2) The brakes should be interlocked mechanically and electrically so that they cannot be applied with the unit connected to the system.

(3) Trip-free devices should be furnished if this feature is not incorporated in the sequence relays.

(4) The choice of air or oil brakes should be given serious consideration. We have oil brakes on all six units and so far it has been impossible to make them oil-tight.

(5) The inherent characteristics of each individual device should be thoroughly known in order that under the different ordinary conditions which will occur in the actual operation of station they will inherently correct for the variations from normal.

As stated in the foregoing, the supervisory control circuits connecting the control and remote stations must be practically invulnerable. These circuits may be affected whenever a disturbance occurs on the transmission lines, which they usually parallel, and unless special precautions are taken, the control circuits will be inoperative just at the time when they are most needed, and this from an operating standpoint is a very serious condition. For nearly a year and a half, serious troubles have been experienced by the Commission, on the control circuits to the two supervisory stations mentioned by Mr. Gerrie. By exhaustive testing and analysis, the inherent weakness has been located and by the installation of protective transformers, now being built, the supervisory circuit should be immune from all transmission line troubles, except a direct stroke of lightning or where a high-voltage line falls on the supervisory control circuit.

The stations in question are Ranney Falls the control point, Dam No. 8 and Dam No. 9. The distance from Ranney Falls to Dam No. 9 is approximately 1½ miles, and to Dam No. 8 is 3½ miles. They are connected by one 44-kv., 3-phase, 60-cycle line which feeds out of Ranney Falls and loops in to Dam No. 9 and Dam No. 8, and thence to Sidney Terminal Station some 20 mi. south, a line which forms part of a 44-kv. network of some 400 mi. of line and which is complicated by several loops. The supervisory connecting wires consist of standard paper-insulated, lead-covered telephone cable located on the same right-of-way as the 44-kv. line, but on a separate pole line at an average distance of 25 ft. from the

high-voltage line, a 20-pair cable between Ranney Falls and Dam No. 9 station and a 10-pair cable between Dam No. 9 and Dam No. 8 stations. Twelve conductors are required under the existing conditions for the control of each station and 66 different operations are performed besides the metering and water-level measurements at each station.

In each of the remote stations there are three generating units which with their respective step-up transformer constitute a unit. The generators in both stations are vertical, water-wheel driven units with direct-connected exciters. The units are of 1400-kv-a. capacity at Dam No. 9, and 2000-kv-a. capacity at Dam No. 8.

It may be of interest to note that the turbines in Dam No. 9 are of the propeller type and the generators are equipped with damper windings while at Dam No. 8 the water-wheels are of the Francis type of runner, and the generators are not equipped with damper windings. Self-synchronizing of the units is employed in both stations. This practise at Dam No. 8, from current literature, would appear as questionable practise, but results have proved it very successful. It should be noted, however, that the generators in this station have solid field poles.

Induction was first thought to be the trouble, but an analysis indicated that the burn-outs were much too severe to be caused by it under the existing conditions. It later was discovered that on account of the high-voltage neutral being grounded to the station ground at the control point, the lead covering of the supervisory cable was acting as a ground stabilizing conductor whenever faults occurred on the high-voltage transmission system with a flow of ground current. By removing the high-voltage neutral ground at the control point approximately 1000 ft. from the station, trouble of this nature was mitigated except where due to a lightning-arrester discharge or an insulator spillover at the control or either of the remote stations. The system is operating at present under this hazard with operators maintained in both the remote stations. The protective transformers referred to in the foregoing are designed to make the supervisory cable immune from these troubles.

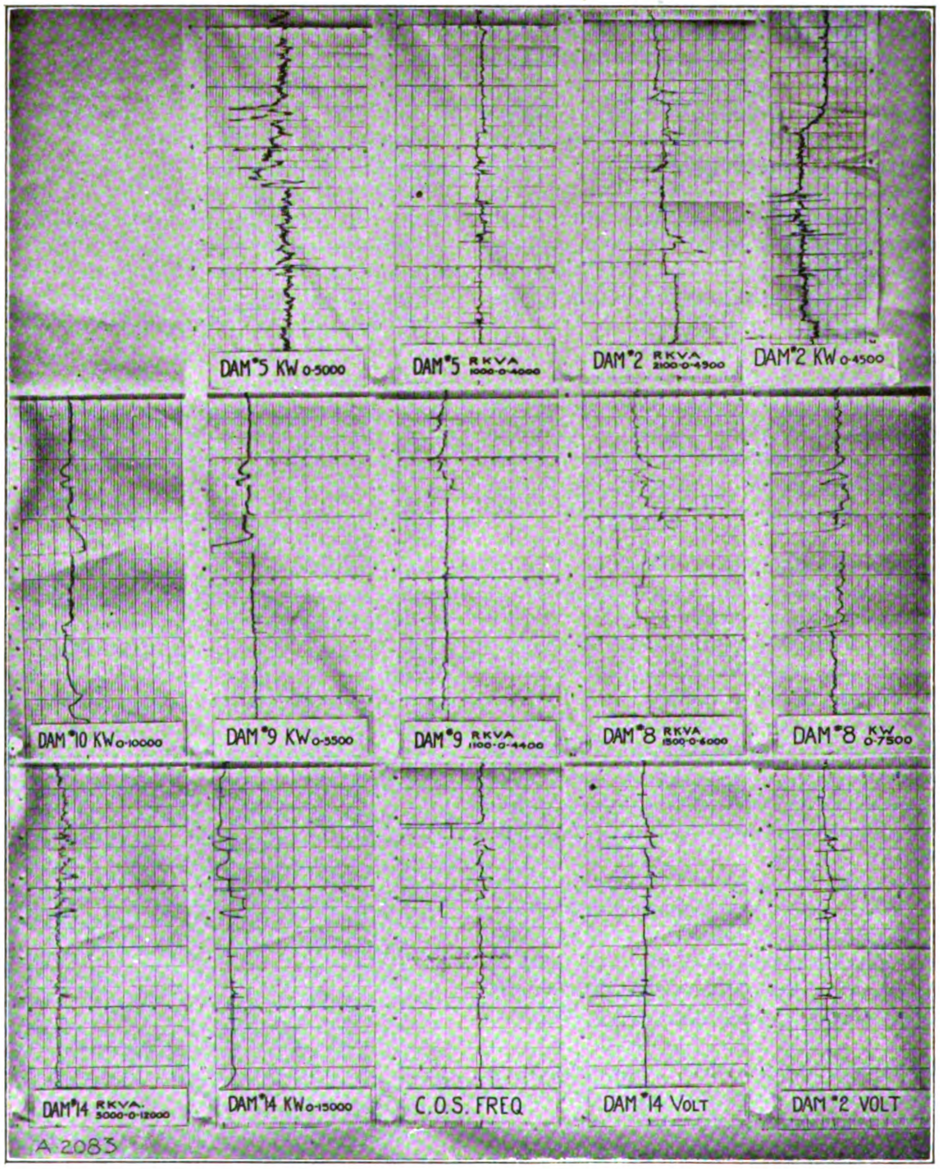

Fig. 1

For a period of approximately three months during the past winter, the supervisory control was not in operation. When again placed in service, very little trouble was experienced, and only a few cases of mechanical trouble have occurred in the past two months, a performance very creditable to the equipment.

Dependence is not yet placed in the control and operators are still on duty at the remote stations.

In attacking the problem of the installation of operation of the automatic and supervisory stations, an effort was made by the Commission quickly to acquaint its staff of engineers and operators who were to be directly responsible for the installation and operation of these stations with the details of their connections by preparing unit diagrams of correlated devices; *i. e.*, the automatic connection diagrams as supplied by the manufacturing companies were split up. A corresponding drawing of the governor was also prepared. These have been of untold value and still form a ready reference.

Fig. 1 shows a number of graphic meter charts taken during a period of several hours on the morning of September 18th, 1925, at which time there was a severe electrical storm over the entire system. Note how closely the frequency is regulated even during such a time. This group of charts forms a very interesting study of this system's operating characteristics.

Fig. 2 shows a number of oscillographs which form part of the test on the performance of these stations.

I feel that much more successful tests could be obtained now, as a decided improvement has been made in the regulator and governors and speed control adjustments since the tests referred to in the foregoing were conducted and these changes would vitally affect the performance of the equipment. The oscillographs shown refer only to Dam No. 9 station; those obtained for Dam No. 8 station were equally successful, the disturbances of course being considerably different due largely to the differences in design of both generators and turbines. It may be interesting to note that on a number of the oscillographs referred to, as many as five quantities are readily readable on a three-element oscillograph. For measuring speed on these, a chronograph method, similar to that used by Mr. J. A. Johnston but developed independently by the hydro engineers, was used with success.

A. G. Darling: The problem of self or automatic synchronizing has been very much discussed. I want merely to cite two cases of self synchronizing under very difficult conditions which have been successful.

One case was in a paper company which uses power to drive paper machines which require very close speed regulation. This particular case involved a 750-kw. steam turbine generator and an auxiliary 3000-kw. steam turbine generator. The first was non-condensing and was used to supply power directly to the paper machines while the second was put on the line when the power company did not have sufficient power available to furnish power for the balance of the mill. They were operated in parallel.

The operator in charge had great difficulty in bringing in the 3000-kw. machine by the usual method of exciting first and then synchronizing by a synchroscope without breaking the sheet on the paper machine.

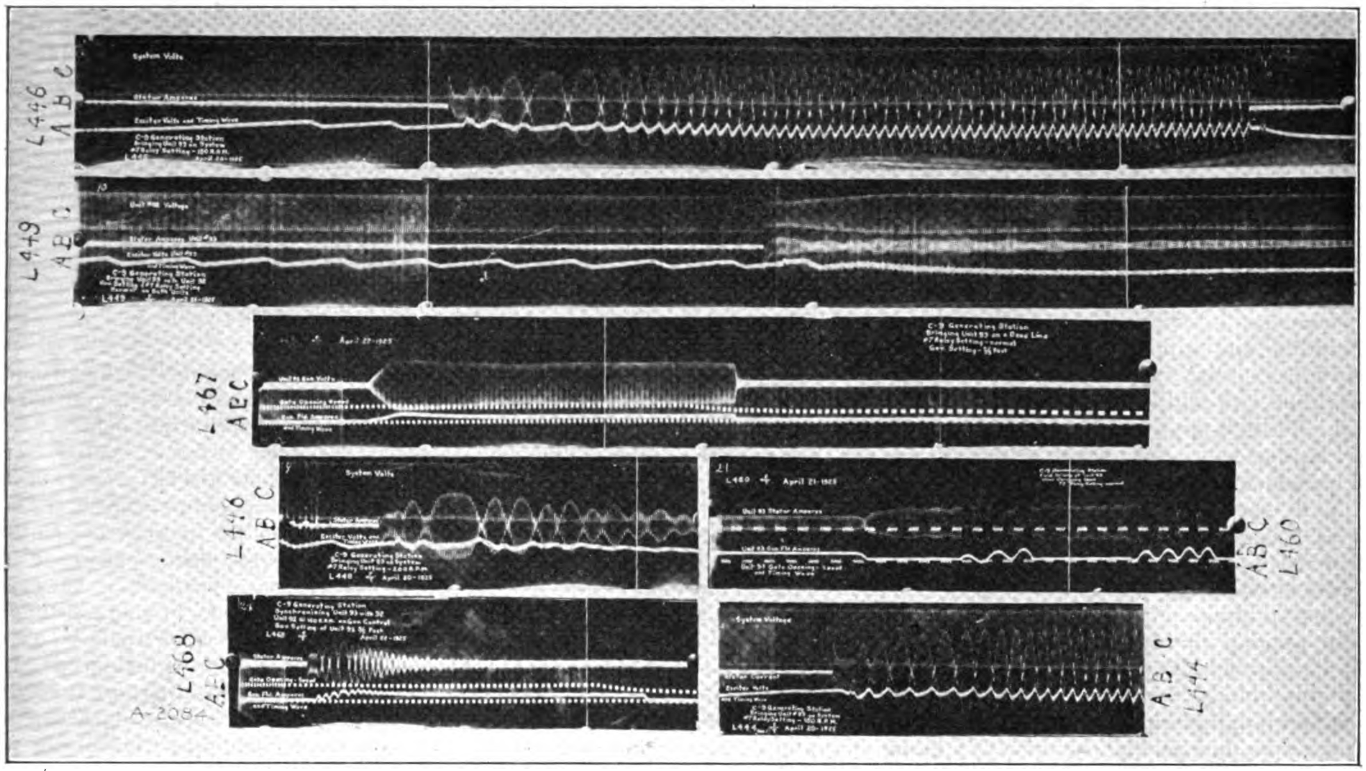

Fig. 2

He asked for advice on the point and it was suggested that he bring in the 3000-kw. unit by the self-synchronizing method, that is to say, put it on the 750-kw. turbine without its field being excited. His success after that was uniform. He did not have to depend on the operator's accuracy and his sheet was not broken when synchronizing the 3000-kw. machine.

The second case is of another paper company in the middle west which operated two steam-engine-driven paper machines. In addition to the paper machines, 200-h. p. synchronous motors were directly connected to the engines.

Initially these two motors were supplied from the power company in the vicinity without a great deal of success because the speed regulation of the power company system was too wide to permit paper being made consistently for 24 hrs. The paper company owned a hydroelectric development nearby and installed there three 2500-kw. units. One unit was on the line all day long and the other two units came on and went off as the water level increased and decreased during the day, so that there were two operations of synchronizing and two of coming off the line during every 24 hrs. These machines were put in parallel with

the 200-h. p. synchronous motors on the paper machine drive and were self synchronized.

The plant has been operating for two years, I believe, and they have had no difficulty with breaking the sheet of paper when the 2500-kw. units are put on in parallel with 200-h. p. motors.

F. V. Smith: Mr. Darling's experiences with the difficulties encountered with manual synchronizing and the success of self-synchronizing methods are interesting and bring out strongly the necessity for very accurate synchronizing in some cases. The average paper-mill operator cannot always be expected to hit the mark and it is apparent that if a machine is excited and thrown in out of phase it will produce more disturbance than if put on the line as an induction motor. With a reliable means of assuring proper phase relations as is done by the automatic synchronizer the disturbance would be reduced to practically zero.

Mr. Gerrie also has mentioned successful self-synchronizing with machines without dampers. This is sometimes a possibility and should always be tested out in case of old machines that are to be made automatic and are not provided with dampers. In certain cases with a large number of solid poles sufficient current will circulate in the pole faces to pull the machines into step. This is the exception rather than the rule, however.

Mr. Gerrie and Mr. Publow have brought up a number of points which will be covered in order.

As to the economy of supervisory control installations, every problem has to be treated separately. Proper inspection and maintenance is, of course, necessary but any operator capable of testing and adjusting relays should be able to handle the supervisory control without difficulty. There are many systems operating with only one or two plants and finding it quite economical. There is no reason why the governors should not function as satisfactorily after years of service as any other piece of equipment.

As to regulators, by far the most satisfactory arrangement is to have a separate regulator for each machine. Proper division of reactive current can then be secured without any difficulty by proper cross compensation; any instruction book on regulators will explain this connection.

In general, the battery should be charged from rectifiers. This is particularly true where a regulator is used on the exciter and the voltage varies over quite a range. The control for rectifiers is quite simple and most suitable for automatic stations. There is no fundamental objection to a motor generator except the additional expense and complication of control which is not in general felt to be justified.

The integrating type of remote metering should be perfectly accurate while the graphic type should be accurate within three per cent which is comparable with any graphic meter. The various types of metering schemes available have their application depending on the kind of indication required and the length and characteristics of the control circuit. In adjusting load the time lag in the meter should be no greater than that in the governor and gate mechanism and it is difficult to see that this is of any particular moment. Any operator would naturally wait for a few seconds after changing load before making another adjustment.

Both Mr. Gerrie and Mr. Publow refer to the failures of supervisory-control cable when faults occurred on the high-tension line owing to lack of foresight in locating the station grounds. It is to be hoped that this experience will prove of value to others.

The question as to the setting of low-voltage relays and the number of annunciators provided can always be adjusted to the satisfaction of all concerned.

As to the multiple-unit stations, where individual regulators and direct-connected exciters are used with rectifier control for the battery, the problem is not difficult to handle. The parallel operation of regulators has already been mentioned.

The direct-connected exciter is particularly advantageous because of the elimination of all starting or governor control for a separate motor-generator set or water-wheel exciter together with the protective apparatus that would have to be provided. The time of starting and getting on the line would also be delayed by the time necessary to start the exciter and another link would be added in the chain which should be made as simple as possible in all automatic stations.

Mr. Publow brings up a number of points that have already been covered. The shutting down of a generator due to high frequency on the system has not been encountered to any extent. It is difficult to say why it would not be satisfactory to set up the governor to the top frequency limit so that the automatic generator would tend to take load rather than shut down and then by means of supervisory control the load can be adjusted afterwards to suit.

The application in which exciter voltage is used to determine approximately synchronous speed is one in which the automatic generators are small in comparison with the whole system and accurate adjustment is not necessary as the current surge on closing the breaker is unimportant. This does not interfere with over-voltage protection of the exciter.

The arrangement of protective tubes has already been described in the paper; there is nothing further to add on this point.

Mr. Publow has listed a number of points on which successful supervisory control is dependent. I find myself in hearty agreement with these; they are all incorporated in the code type of supervisory control. Also automatic switching is in general in accordance with the factors mentioned.

As to the desirability of grounding the battery, it is found much more satisfactory to keep the battery circuit entirely isolated so as to prevent any faulty operation by accidental grounds.

Difficulties with the oil dash-pot for governor control have never been found to be of any importance and as far as is known it has never been felt necessary to use a motor mechanism.

The same feeling exists as to control for the governor motor; while it is open to objection at times the change suggested has never been felt warranted. There is no objection to it, however.

It is not possible to give a definite figure for ground resistance; that which would be satisfactory in some cases would be quite unsatisfactory in others. The essential point is that the ground resistance should be such that is is considerably less than the path provided through the supervisory circuit which can be determined for any particular case.

There is a last important point which must be considered and which has been mentioned by both discussors, and that is the relation of the manufacturer to the installation and operation of the equipment. While it is the duty of the manufacturer to furnish the apparatus with complete information, it is a question whether it is desirable that he should take care of all the installation and initial operation. As the operating company's men must ultimately take charge of everything and also correct troubles when they occur, there is no way for them to become better acquainted with the details than in the erection stage and the more they have to do with it the better; they will then feel enough confidence to go ahead when difficulties occur. Many operators feel that there is something mysterious about automatic control. There is no justification for this attitude and there is nothing in automatic and supervisory control that cannot be handled by intelligent operators without constant appeals to the manufacturer.

These tests were made on 1400-kv-a, 180-rev. per min. units driven by propeller-type turbines.

In L 446 it is interesting to note what a slight disturbance was noticeable in the system voltage when a unit was placed on the line and failed to "pull in" due to its slow speed. The machine was thrown on the system when it had a speed of 150 rev. per min. Curve *A* shows exciter voltage and timing wave. Curve *B* shows stator amperes. Curve *C* shows system voltage.

L 499 shows a unit synchronized with a duplicate unit carrying

no load and although an abrupt voltage disturbance occurred it was practically damped out in a second. Curve *A* shows exciter voltage on the unit being synchronized. Curve *B* shows stator amperes on the unit being synchronized. Curve *C* shows voltage of the running unit.

L 467 proves how smoothly and quickly an isolated unit can be placed in service on a system. Curve *A* shows field amperes and timing wave. Curve *B* shows gate opening and speed. Curve *C* shows generator voltage.

In L 448 where the unit failed to "pull in" due to overspeed, there will again be noted the slight voltage disturbance which occurred and also the peculiar alternately large and small stator-current disturbances. The machine was connected to the system when running at 200 rev. per min. Curve *A* shows exciter voltage and timing wave. Curve *B* shows stator current. Curve *C* shows system voltage.

A severe test of field failure under load is shown in L 460. Apparently there was no tendency for this unit to pull out of step at the load carried. Curve *A* shows gate opening, speed and timing wave. Curve *B* shows field current. Curve *C* shows stator current.

The test shown in L 468 was performed to illustrate the ability of a unit (No. 93) to pull into step with a duplicate unit (No. 92) running under no load at a reduced frequency. Unit No. 92 was running at 160 rev. per min. on governor control. The governor of No. 93 was set for highest speed. Curve *A* shows generator field amperes and timing wave. Curve *B* shows gate opening and speed. Curve *C* shows stator amperes.

L 444 shows the failure of a unit to pull into step when connected to the system while running at 150 rev. per min. Curve *A* shows exciter voltage and timing wave. Curve *B* shows stator current. Curve *C* shows system voltage. This, it should be noted, is a duplicate of L 446, but the initial disturbances are quite different.

STEEL-ENCLOSED POWER RECTIFIERS[1]

(MARTI)

NIAGARA FALLS, N. Y., MAY 27, 1926

R. H. Wheeler: Mr. Marti has been quite conservative in many statements in his paper. Progress in the development of the rectifier, together with its applications in commercial service, is going forward at a rapid rate. One thing that Mr. Marti did not bring out, and which from my angle is interesting, is that the rectifier is a piece of machinery which has the ability of being placed in practically any available space, rather than demanding a machine hall with ample provision for ventilation. The floor loadings required by the rectifier are less than 200 lb. per sq. ft., and permit of the rectifier being installed directly without special foundations.

I wish to confirm the statements of Mr. Marti as to the absence of noise. There are no reciprocating parts other than that of the vacuum pump which, when it is running, makes a chatter, but when one realizes that it is operated by a fractional h. p. motor, it is at once evident that the noise is not great and can easily be muffled by a cover if absolutely noiseless operation is desired.

Otto Naef: Mr. Marti mentioned that in order to obtain close d-c. regulation, special equipment must be added, and he quoted the interphase transformer, or absorption coil, as it is often called, as one of the means.

After considerable research, Brown Boveri has succeeded in bringing out a zig-zag-connected transformer winding which gives the same close regulation as is otherwise only obtained by the use of an interphase transformer. Because of the somewhat larger transformer required, this solution is not necessarily cheaper than the older method, but it has the advantage of greater simplicity.

1. A. I. E. E. JOURNAL, Sept. 1926, p. 832.

D. C. Prince: Mr. Marti refers to an ingenious seal as having made possible the successful steel-tank rectifier. The accompanying Fig. 1 shows one of these earliest types of steel rectifiers, built about 1908. The operation of these early rectifiers compared favorably with that of any of the newer types.

In saying that the quantitative relations on which rectifier design is based are well established, Mr. Marti doubtless refers

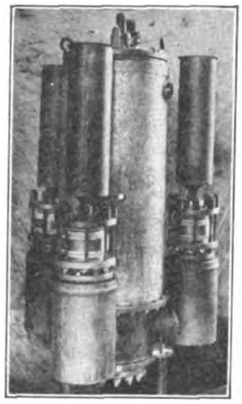

FIG. 1—EARLY TYPE OF STEEL-CLAD MERCURY-ARC RECTIFIER (1908)

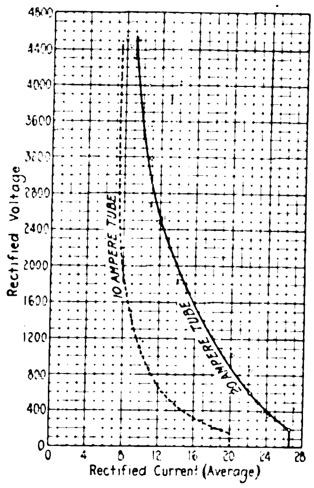

FIG. 2—VOLT-AMPERE CURVES MADE FROM GLASS RECTIFIER

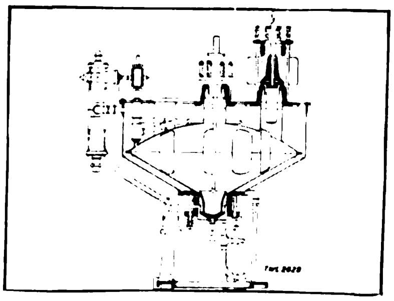

FIG. 3—A. E. G. TYPE OF RECTIFIER

to the circuit characteristics. As far as I am aware, no data for metal rectifiers have been published including reproducible curves between volts and amperes at which arc-back occurs, such as shown in Fig. 2 herewith. This curve was made from a glass rectifier.

The extent to which engineering opinion differs regarding the fundamentals of steel rectifier design is brought out by comparing the accompanying Fig. 3 with the Brown Boveri

rectifier shown in section in Mr. Marti's Fig. 10. It will be observed that the A. E. G. type has no arc guides and no condensing dome nor any elaborate anode hoods. The A. E. G. rectifiers are regarded as highly successful, and there are many installations. I understand that they have little if any seal trouble.

Even the figures accepted for some years for cathode drop have recently been overthrown[2]. The present figure is about 10 volts, part of which is consumed as latent heat of ionization of the mercury vapor. This part is responsible for most of the heating at the anodes where recombination occurs.

Too much cannot be said in praise of the paper by Messrs. Daellenbach and Gerecke referred to by Mr. Marti as the basis for his circuit theory. The part quoted by Mr. Marti, applying to regulation, is limited to the case of no resistance and reactance only in the individual anode leads. It is also limited to the case where not more than two anodes carry current simultaneously. The original paper by Messrs. Daellenbach and Gerecke is much more complete and will repay careful study, although the analytical methods pursued become rather involved for the more complicated cases met in practise. Their paper has been very useful in my work.

E. B. Shand: A number of years ago the Westinghouse Company did a great deal of work on steel-tank rectifiers, and a resumé of this was given by the late B. G. Lamme in the discussion of "Power Rectifiers" by Milliken, *Proc.* Assoc. Iron & Steel E. E., 1921, p. 645. In this work, we started using mercury seals with the steel tanks in 1908 and developed them in 1909 to the general type used at present by the Brown Boveri Company. In 1915 considerable amount of work was done on plastic sealing cements. Our experience at that time indicates that the tightest possible joints can be made by this means, although the application to commercial use presents an additional problem. At this time we were able to operate rectifiers of commercial size with these seals for periods of somewhat over a month, without pumping. Welded tanks were introduced in 1910.

I might add that the wire resistance gage for high vacuum, which is mentioned in Mr. Marti's paper (Figs. 16A and B), was developed during this work in 1916 or '17. I still have in the laboratory a gage of this sort which dates from the above period.

A single auxiliary anode was used for both starting and exciting of the rectifier. An external source of direct current was supplied to this anode. Small rectifiers are now available for the purpose of furnishing this power and which require no attention of any sort.

In connection with the bibliography, I believe that the interesting papers of M. Giroz[3] should be included.

In connection with the tabulated data on the sixth page of Mr. Marti's paper, I notice that the case of three single-phase transformers connected in star has not been included. In this case, the current ratios in the transformers secondaries and in the primary line are similar to the case of the delta-connected transformer with the balance coil.

It might be added that the balance coil or interphase transformer was developed in connection with the earlier work of the Westinghouse Company by Mr. C. L. Fortescue.

S. Q. Hayes: A point that may be of interest to a good many people is that the electrification of the railways in Japan now being carried out at 1500 volts direct-current has quite a large number of substations, and some of those substations have synchronous converters, some have motor converters, some have motor-generator sets, and some have mercury rectifiers; and they are operating the whole system together in parallel.

F. A. Faron: Mr. Marti infers in his paper that arc-backs occur during the bake-out or forming period. Are we to understand that arc-backs never occur during regular operation?

On the twelfth page Mr. Marti refers to the possibility of a rectifier starting to take peaks of such short duration that converter units would miss these peaks. What he says about starting may be true, but why should a machine be started to take care of such peaks? This is what the overload capacity of the machine is for. And if the load goes beyond this allowable limit, it is not usually a useful one and devices are provided to take care of limiting the output. With reference to regulation, it should be noted that it is possible, as brought out by Mr. Prince, to build rectifier equipment with practically flat d-c. voltage characteristics from low load to full load.

Mr. Marti indicates that traction loads are handled by converting equipment with drooping characteristics. This is not quite correct, for in 90 per cent of the traction substations in this country, compound-wound machines are used, having practically flat voltage characteristics from no load to full load.

Fig. 20 is apparently based on a maximum rated unit. Experience has shown that railway operators are not particularly interested in a maximum rating but in what the machine will do for a period of about two hours, which is the usual duration of peak service. This is fairly well brought out in Curve 21-*B*, on the same page. In comparison with Curve 20, it should be noted that a standard 500-kw. railway converter, for instance, would be rated 750 kw. for two hours and three times load for one minute.

Does Mr. Marti intend to convey that all equipment including rectifiers, transformers, auxiliary devices and switchboard for 600 volts take about the same space as complete converter equipments, or does he mean only the tanks? I am of the opinion that the complete installation of rectifiers, transformers, reactors, accessories, switchboard, etc., occupy more space than equivalent converter capacity for this voltage. I agree with Mr. Marti that, for higher voltages, the complete rectifier units require less space than converter units.

In traction work it is quite common to provide single-phase transformers which give the possibility of open-delta operation of converters in cases of emergency. This feature is not desirable in connection with a rectifier.

Under the subject of starting it should be noted that in automatic stations it is usually found more economical to remove the transformer from the line when the station is not in operation, to save the transformer excitation losses.

I have been unable to check the figures given under the heading *Efficiency*, as the converters offered by American manufacturers have higher efficiencies than those shown on the curves of Fig. 21A and actually cross the efficiency curve of the rectifier at about 600-kw. point, and show somewhat over one per cent higher efficiencies of the converter than Curve *A*, which reduces the hypothetical saving set forth by Mr. Marti.

I am fearful that "automatic control" is a rather abused and misunderstood term, but it should be understood as applying to a station wherein all functions of operation are performed without the aid of an attendant.

Certain functions necessary to the operation of a rectifier, which are absent with converter operations, must be properly incorporated in the control, and protection provided should the sequence of the device in operation be other than that intended.

There will be certain temporary shut-downs during operation which the control must take care of; such, for example, as low a-c. power supply, single-phase operation, overheating of the rectifier, failure of the exciting arc and overheating of the transformers.

Furthermore, such conditions as failure of cooling-water supply, continued arc-backs, heavy sustained overloads, etc., require that the equipment be shut down and locked out, and

that the automatic control be designed to carry out these functions.

Incidentally, a very careful investigation has convinced me that there have been no rectifiers built which will not arc-back if the vapor-pressure conditions in the neighborhood of the anode are not correct.

Mr. Marti says: "For instance, a railroad equipped for using 600-volt direct current can be changed to 1200-volt direct current merely by changing the connections of the transformers and making no changes whatever in the rectifiers." It is one of the advantages of rectifiers to be able to use the same unit for higher voltages, provided it is suitably insulated;—but unfortunately the substation is only one thing that must be changed; in fact, changing the substation voltage, even where converters are used, is a relatively small expense compared to insulation of line, sectionalizing switches, motors, control, etc.

The substation of the average traction system in this country represents only an investment of about 20 per cent of the total investment in electrical apparatus and of this the converter and transformer represents about one-half, and it can readily be appreciated that changing the voltage at the substation is a small part of the total cost.

There have been cases in the past where it was as simple to arrange substations originally designed for 600 volts and which contained two or more machines to provide for 1200-volt operation, merely by insulating the base of one machine and connecting the units in series; in fact some of the first 1200-volt roads in this country contain substation equipments arranged in this way. I would therefore suggest qualification of this statement.

In another sentence of this paragraph attention is called to the rectifier being able to withstand "instantaneous currents of even three times the normal value." It should be noted that standard, 500-kw., synchronous converters for railway service are guaranteed to stand three times normal load for one minute.

From this discussion it might be assumed that I oppose rectifiers as against synchronous converters, but such is not the case. Rectifiers are a comparatively new type of apparatus in this country, and their operation will be watched with interest, for undoubtedly there are applications where rectifiers are desirable. There are some points in Mr. Marti's paper, however, with which I cannot agree.

Albrecht Naeter (communicated after adjournment): Having had the privilege of making an acceptance test of one of the early Brown Boveri rectifiers in the United States, the writer was very much interested in this article by Mr. Marti, for he found that in the early stages of operation, after the forming period of the electrodes of the particular set tested, considerable difficulty was encountered by the operating staff in maintaining a good vacuum. Frequently only a few minutes after a vacuum determination had been made by the MacLeod type of gage the vacuum would drop quickly to a value considered unsafe for continued full-load operation. Fortunately the development of the novel electric hot-wire vacuum gage, according to the paper under discussion, has helped to ameliorate this situation because of the further researches made possible through it. The writer feels that, from the standpoint of the operating personnel, the vacuum-gage indication should be a continuously recording one that is visible at all times. Naturally this would be taken care of through the automatic feature of the vacuum-pump set in complete automatic sets, provided the rectifier is kept out of service without an operator's attention when the vacuum is low.

The writer recognizes the advantages of rectifiers, and agrees heartily with their use for higher voltages such as are common in railway work. It seems that undue stress has been laid upon the relative merits of these rectifiers and synchronous converters. Mr. Marti points out in his paper that the best field of application of these rectifiers is that of higher voltages,—higher than those of the commercially practicable synchronous converters. If the efficiency curves in Fig. 21 had been plotted for 240-volt machines, instead of 600-volt, and for the same kilowatt rating, the rectifier would probably have been found at a disadvantage. The rectifier would have shown up still less favorably if the overall efficiency of a 3000- or 4000-kw. synchronous-converter set of 240 volts had been compared to that of the several rectifiers required for the same output. A number of years ago the technical press was full of articles on the relative merits of motor-generator sets and synchronous converters, on the assumption that was then accepted that these machines were equally applicable to the same field; but now it is recognized that each has its particular advantages that make its application desirable in certain cases.

Inasmuch as the author places emphasis on the merits of rectifiers, it would have been well, for the sake of completeness of the article, to summarize some of the disadvantages of rectifiers, particularly as compared to the converter, (since he carries out that comparison), such as low efficiency at 240 volts, limited maximum sizes now available, lack of neutral for three-wire systems, etc.

O. K. Marti: Referring to Mr. Prince's remarks regarding engineering opinion concerning the design of various types of rectifiers, I should like only to call attention to the fact that the Brown Boveri rectifier, a cross-section of which is shown in my paper in Fig. 10, outnumbers the A. E. G. type shown by Mr. Prince, in the proportion of ten to one, and it can be inferred from this fact that the eventual development will probably result in a type similar to the one shown in Fig. 10 in my paper.

With reference to Mr. Shand's discussion, it was interesting for me to note that two companies have followed, independent of each other, practically the same lines in developing the steel-enclosed rectifier. Regarding the two systems of ignition, it is certain that the a-c. system of ignition and excitation is far superior to the other system, since it does not require an auxiliary d-c. generating device.

I am obliged to Mr. Shand for the additional references for my bibliography and, at this opportunity, I should also like to mention a series of articles by Dr. Schaefer, published in the BBC Mitteilungen, 1919, Nos, 3, 5, 7, 8, and 9; incidentally, these articles discussed for the first time a method of compounding mercury-arc rectifiers similar in principle to the one on which Mr. Prince's paper is based.

To Mr. Faron's remarks, I should like to add that, under normal operating conditions, a rectifier will not back-fire, but there is no question that back-fires may occur under abnormal conditions, such as those caused by inadmissibly high overloads, poor vacuum due to leakage or the use of improper material in the manufacture of the rectifier.

Regarding starting, I wish to bring out the fact that a rectifier can be started in less than two seconds, being then immediately able to pick up load. This surely is an advantage over a rotary converter which requires about thirty seconds for starting, and therefore cannot take care of any load before that time. To a railroad company, for instance, it means a great deal to have no delays of trains caused by lack of power.

Referring to the over-compound characteristics of traction conversion devices, it would have been interesting if Mr. Faron would have mentioned not only the fact that 90 per cent of the installed synchronous converters have over-compound characteristics, but would also have stated what was the percentage of converters with such a characteristic ordered during the last year. He would probably have found that it was about 50 per cent. This would have given a true picture of the status of the matter. Moreover, it would have been interesting if he would also have given the relative advantages of the two characteristics for railway service. I, personally, cannot see any, but will state here some of the many advantages of a drooping characteristic. It is realized by most railway men that the latter characteristic

guarantees a far more flexible operation and a far better distribution of load between neighboring substations. This results in a better load factor, allows giving the same service with a lower station capacity, reduces the losses in the feeders, and does away, in most cases, with a load-resisting device. This last means nothing else than a complication of the system and a great waste of power as long as it is in operation.

As to the floor space needed by a rectifier, it is true that the actual floor space required by a 600-volt rectifier, with all its auxiliaries, is somewhat more than for a rotary converter of the same voltage and capacity. However, considering the smaller weight of the rectifier, it is possible to utilize the space available for the converting units more effectively,—for instance, by mounting the rectifier and its auxiliaries on different floors of a building. Moreover, for the same reason, a lighter foundation, and also a lighter building construction, can be used, so that both in the erection of new buildings and in the adaptation of old buildings to substation uses, a material gain is effected.

With reference to the efficiency curves shown in Fig. 21A of my paper, I should like to mention that they were derived from data published by American manufacturers, including the stray losses according to the A. I. E. E. Standards, given as one per cent of the output. The efficiency of the transformers was taken to be the same for both the rotary converters and the mercury-arc rectifiers.

Regarding the automatic control, Mr. Faron states that auxiliaries will have to take care of abnormal conditions; but this holds true also for rotary converters. I wish to point out again that the automatic control of a rectifier is much simpler than that of a rotary converter, as most of the operations necessary in starting a rotary converter,—such as step-changing, raising and lowering the brushes, polarity check, etc.—are absent in the starting of rectifiers, for which the total starting operation consists of the natural sequence of closing the a-c. breaker, the automatic ignition, and closing the d-c. breaker. Due to the valve action of the arc, the protection which Mr. Faron recommends is not needed for the usual a-c. voltage supply.

I fully agree with Mr. Naeter's statements, and I think he is more than right when he compares with the present conditions the state in which electrical engineers were when the rotary converter came into prominence to take the place of the well established motor generator. There is no question but that a rotary converter will in many cases have an advantage over a mercury-arc rectifier, just as a motor-generator set shows outstanding advantages over the rotary converter in certain applications.

MOTOR VEHICLE LIGHTING TESTS

An interesting series of lighting tests were conducted in connection with the meeting of the joint Steering Committee of the Illuminating Engineering Society and the Society of Automotive Engineers which was held during the recent convention of the S. A. E. at French Lick.

Seven cars were equipped with special test headlighting equipment consisting of two pairs of headlamps on each car giving a graduation of vertical and horizontal spreads of light over a wide range. Means were provided also for securing asymmetric distribution (low beam on the left and high beam on the right).

The demonstrations attracted considerable attention in that they showed the wide range available which could be made to conform to the state requirements while meeting the tastes of different car operators. A large number of persons participated and it is hoped that their comments will aid the committee materially in guiding future work.—From I. E. S. *Transaction*, July 1926.

ILLUMINATION ITEMS

By Committee on Production and Application of Light

INSIDE-FROSTED LAMPS

A Discovery Promoting Efficient Light Production

Growing appreciation of the importance of good electric lighting during the decade between 1915 and 1925 led to much wider use of diffused light. Diffusion by enclosing the lamps in translucent glassware and adequate shades and by using other devices was a vague subject to the general public.

Consequently with the advent of the high-efficiency tungsten lamp, the manufacturers endeavored to conceal the bright filaments by etching or frosting the bulbs. Frosting on the outside of the bulb proved objectionable for two chief reasons. It was wasteful of light, offsetting, to a slight degree, the great progress made in increasing the light-producing efficiency of the filament. Also, outside-frosted lamps collected dust and dirt quickly, which could not easily be wiped off.

For many years lamp engineers realized that a lamp frosted on the inside, instead of on the outside, would be very desirable. It would not only present a smooth outside surface and be as easily cleaned as a clear lamp, but a lighter frosting would suffice, increasing the efficiency. The trouble with the idea was, that when a lamp bulb was frosted on the inside, it became as brittle as an egg shell. For twenty years engineers wrestled with this problem to no avail, until Marvin Pipkin, of the National Lamp Works of the General Electric Company solved the difficulty. The method is simple.

A strong solution of acid is first sprayed into the bulb, which etches it. In this condition the surface of the glass is made up of irregular little projections with many sharp angles. While the glass is still in this state it is extremely weak, and a slight pressure or bump is sufficient to shatter it. So far, the process is similar to former attempts at inside frosting. The difference lies in the strengthening process, which is the application of another acid solution, somewhat weaker than the first. This second treating rounds off the sharp edges and minute projections, giving the glass an appearance, under a powerful microscope, of being made up of tiny hemispheres. The bulb is now strong again,—just as strong as it was originally.

Superiority of the inside-frosted lamp over the outside-frosted, so far as light transmitting characteristics are concerned, also needs explanation. In the outside-frosted lamp, light from the filament travels through the gas or vacuum to the wall of the bulb, then through the glass, on the outer surface of which it meets the frost. Then, depending upon the direction of the plane of the particle of rough surfaces, the beam either passes on through the frosted surface as useful light or is reflected back through the glass layer. Each time the light passes through the glass, a certain amount of absorption takes place.

Diffusion of the light by the inside frost is obtained

by prismatic refraction with comparatively little loss. In fact, the inside frost allows an even greater portion of the light to pass through than does a similar frost on the outside of the lamp. This is due to the fact that the multiple internal reflections are not so numerous in the inside frosted lamp because the rough, interior surface does not reflect any considerable portion of the light back and forth inside the lamp, as happens with the outside-frosted lamp. Moreover, the relative absorption of the inside frost does not increase so rapidly with the life of the lamp as does that of other diffusing media.

For these reasons, then, the inside-frosted lamp is only about two per cent less efficient than a clear lamp, contrasted with a loss of efficiency of three to four times this much in the old style sand-frosted and sprayed lamps.

Another great benefit of the discovery of inside frosting is at once apparent when it is realized that now the manufacturers need only one type of lamp of each wattage instead of lamps with several different finishes. This is beneficial not only from the standpoint of economies resulting from the increased use of automatic machinery and the decreased investment in lamps lying idle in warehouses and on dealers' shelves, but also there is still greater benefit for the public in general. Since the inside-frosted lamps give practically as much light as clear lamps, they can be used to replace clear lamps for every ordinary use. This means that wherever, because of ignorance or carelessness, lamps are used without proper shades or glassware, the inside-frosted lamps will afford a certain degree of eyesight protection. Furthermore, wherever lamps are properly shaded, the inside frosting will eliminate sharp shadows and striations, with negligible loss of efficiency.

The invention of the inside-frosting process, of the same order of importance as the invention of gas-filled lamps and tipless lamp construction, is one more example of the value of systematic research, persistently pursued.

EUROPE ORGANIZES ITS LIGHTING ACTIVITIES

Within the last two or three years an increasingly greater amount of attention has been given in various European countries to the promotion of better lighting in factories, homes offices and the like. Lighting demonstrations, illumination courses, technical and advertising literature are all being pressed into service to carry the message of good lighting to the people of many foreign lands. A list of some of the European countries where this work is now being carried on intensively would include England, France, Germany, Italy, Austria, Sweden, Czechoslovakia, Belgium, Scotland and perhaps some others.

Holland has only recently organized an Illuminating Engineering Society which is supported by a number of able and prominent men.

Like some of the others, this new society has the following objects:

1. To educate the public in the art of illumination by lectures, demonstrations, publications and the like.
2. To demonstrate proper and practical ideas about lighting to pupils already in school.
3. To encourage the application of proper lighting in practise by giving information and advice to those who desire it.
4. To bring about new applications and improvements in lighting through the standardization of accessories and development work.

It is being organized to accomplish these things by means of permanent demonstration rooms, illuminating engineering and general educational service.

A lecture given by Mr. C. P. Jensen before the thirty-first Congress of the V. D. E. (Association of German Electrical Engineers) in June, at Wiesbaden dealt with the German Society of Lighting Economics from the point of view of the electrical organizations in Germany. It was a plea to them to unite in a cooperative movement for a broader understanding of lighting economics as a means of rendering a greater service to the users of light.

Once a suitable neutral basis for the cooperation of the electrotechnical industry has been created in the field of illuminating economics, there remains only the question of its practical influence on the broad masses of the light-consuming public with the view to increasing the service of this great electric lighting industry.

It is hoped that a growing demand for electric lighting service will be established and that through increased production and other advantages to be derived from better lighting, a great economic good will be accomplished.

Europe today, says Mr. Jensen, is setting out on a program of electrical standardization similiar to that which has meant so much to electrical progress in America. Plans are being made to standardize the voltages of lighting circuits and to decrease the number of lamp types.

These German activities received their impetus over a year ago with the opening at Berlin of the new "house of light" containing a group of lighting demonstration rooms. Since then some 50,000 people have been initiated there into the "mysteries" of good lighting. Furthermore, many well attended illumination courses have been given and these have helped to spread the idea of the advantages of better lighting.

TREND OF ELECTRIC LIGHTING

Significant are many of the trends shown in the annual report of the National Electric Light Association's Lamp Committee. In three years the average wattage of lamps consumed has risen from 55.6 to 57.6; the percentage of exactly 115-volt lamps has risen from 42.8 to 44.6. The Committee recommends that every member company have a "well organized Lighting Service Department," and that there be permanent lighting demonstration rooms in every city of the country.

Pacific Coast Convention

SALT LAKE CITY, SEPTEMBER 6-10, 1926

"Excellent from a professional standpoint and highly enjoyable socially" was the verdict rendered, by the two hundred and fifty or more members and guests in attendance, upon the Annual Pacific Coast Convention held at the Hotel Utah, Salt Lake City, September 6-10.

The technical program included numerous high-grade papers covering a wide variety of topics, discussions contributed by members and guests were valuable, inspection trips to power plants and other places of engineering interest were well managed, and all the visitors were highly appreciative of the cordial hospitality extended by the Salt Lake City members and the ladies of their families.

Student Activities

The first event of the Convention was a Conference of Counselors and Student Branch Chairmen of the Pacific and North West Districts, on Monday morning, September 6. The Counselors present were: Henry H. Henline, Stanford University; J. Hugo Johnson, University of Idaho; T. C. McFarland, University of California; J. F. Merrill, University of Utah; F. O. McMillan, Oregon Agricultural College; S. G. Palmer, University of Nevada; George S. Smith, University of Washington; Royal W. Sorensen, California Institute of Technology; and J. A. Thaler, Montana State College.

The Student Chairmen present were: F. D. Crowther, Oregon Agricultural College; J. W. Cruse, University of Arizona; Chas. F. Dalziel, University of California; Thomas L. Gottier, California Institute of Technology; Clarence M. Murray, Jr., University of Washington; and Alfred V. Pering, Stanford University.

President Chesney, National Secretary Hutchinson, Vice-President Schoolfield and others interested were also in attendance.

Professor Merrill was elected Chairman of the Conference, and Professor Smith Secretary. There was an interesting and profitable discussion regarding various student activities and recommendations were adopted which will be transmitted to the Board of Directors.

Later in the week the Counselors of each of the two Districts met separately and organized as Committees on Student Activities for their respective Geographical Districts as follows:

Pacific District Committee: Chairman, Professor H. H. Henline, Stanford University; Secretary: Professor R. W. Sorensen, California Institute of Technology.

North West District Committee: Chairman: Professor J. A. Thaler, Montana State College; Secretary: Professor George S. Smith, University of Washington.

Opening Session

The first technical session was held on Monday afternoon and was called to order by Mr. C. R. Higson, Chairman of the Convention Committee, who greeted the members and guests and then presented George H. Dern, Governor of Utah, who delivered an excellent address of welcome. Chairman Higson then presented President Chesney as the presiding officer of the Convention, who in responding, congratulated the people of Utah upon having elected an engineer to the office of Governor.

President Chesney then delivered a brief address relating principally to research and standardization, in which he outlined certain major policies which he believed should be followed by the Institute.

He mentioned as examples of leaders in the research and development work in the electrical engineering field in this country, William Stanley, Nikola Tesla, Benjamin Lamme, and Chas. P. Steinmetz, giving a brief outline in each case of the contributions of these leaders. After reviewing briefly the work done upon standardization in the electrical field in this country, President Chesney continuing said:

"The American Institute of Electrical Engineers for the past twenty-five years, through its Standards Committee, has taken the initiative in the formulation of all the electrical standards of America, and its work is recognized as being authoritative throughout the entire world. Its procedure and its resulting standards during this period have been acceptable to the manufacturing and the consuming interests as well as to the general public. The industry has learned to value and depend upon the A. I. E. E. standards in commercial transactions covering matters of interest to all sections of the electrical industry. It has made no attempt to dictate to industry, but introduces standards on any particular line only when it is clear that all interested parties agree that the step is wise and desirable.

"In the Institute Standards Committee, or in its subcommittees, the manufacturer and purchaser and the general interests come together and develop the required standards in a way which has been generally satisfactory to all the interested sections of the industry. The electrical standards so issued have been identified with the name of the Institute, and its name should be continued in connection with them, and in the interest of simplicity and order it would appear that no other name was necessary. It should be remembered that the Institute as an organization has no interest other than one of public service, which duty the Institute has performed throughout the entire period of twenty-five years at its own expense. The Institute, therefore, in connection with the voluntary formulation of electrical standards, has assumed obligations during the past quarter of a century to the electrical industry and to the public which make it now impossible to discontinue the

present practise or lessen its responsibilities until a more simple and direct method has been devised and demonstrated."

The following papers and discussions were then presented:

The Space Charge that Surrounds a Conductor in Corona, by H. J. Ryan and J. S. Carroll, Stanford University. (Presented by Professor Carroll.) Discussion by Messrs. Harris J. Ryan, H. E. Mendenhall, F. O. McMillan and J. S. Carroll.

110-Kv. Transmission Line Construction of the Washington Water Power Co., by L. R. Gamble, Washington Water Power Co. (Presented by the author.) Discussion by Messrs. C. R. Higson, Harold Michener and the author.

A New 220-Kv. Transmission Line, by C. B. Carlson and H. Michener, Southern California Edison Co. (Presented by H. Michener.)

Effect of Unbalanced Tension in a Long-Span Transmission Line, by E. S. Healy and A. J. Wright, Electric Bond and Share Co. (Presented with lantern slides by Mr. Healy.) Discussion by Harold Michener.

Tuesday's Technical Session

The technical session on Tuesday morning was presided over by Vice-President Paul M. Downing, of San Francisco. The following papers were presented:

The Circle Diagram of a Transmission Network, by F. E. Terman, Stanford University. (Presented by the author.)

Calibration of Lichtenberg Figures, by K. B. McEachron, General Electric Company. (Presented by the author.) Discussion on the above two papers was presented by Messrs. J. Slepian and K. B. McEachron.

Stability Characteristics of Alternators, by O. E. Shirley, General Electric Company. (Presented by the author.)

Synchronizing Power in Synchronous Machines, by H. V. Putnam, Westinghouse Electric & Manufacturing Co. (Presented by the author.) Discussions followed by Messrs. David Hall, C. A. Nickle, F. E. Terman, H. V. Putnam, and O. E. Shirley.

At the afternoon session, Vice-President Downing presiding, the following papers were presented:

Vacuum-Switching Experiments at California Institute of Technology, by R. W. Sorensen and H. E. Mendenhall, California Institute of Technology. (Presented by R. W. Sorensen.) Discussion by Messrs. J. Slepian, D. C. Prince, H. E. Mendenhall and R. W. Sorensen.

Electrical Practise in Lead-Silver Mines in Utah, by Leonard Wilson, Consulting Engineer. (Presented by the author.)

Electricity and Coal Mining, by Daniel Harrington, Chief Safety Engineer, U. S. Bureau of Mines. (Presented by Mr. H. T. Plumb.) Discussion by Messrs. Paul Ransom, H. T. Plumb, D. C. McKeehan and Paul M. Downing; also a communication from F. L. Stone.

Engineering Education: Its History and Prospects, by H. H. Henline, Stanford University. (Presented by the author.) Discussion by Messrs. F. E. Terman, J. H. Johnson, George H. Smith, R. W. Sorensen, D. I. Cone, H. T. Plumb, D. C. Prince, H. Michener, K. B. Miller, F. O. McMillan, G. Ross Henninger, David Hall, Paul M. Downing and H. H. Henline; also a written discussion from L. R. Robinson.

Wednesday's Technical Session

Vice-President H. H. Schoolfield, of Portland, Oregon, presided at the session on Wednesday morning, and the following papers were presented:

Protection of Oil Tanks against Lightning, by F. W. Peek, Jr., General Electric Company. (Presented with motion pictures by the author.)

Fire Protection of A-C. Generators, by J. A. Johnson, Niagara Falls Power Co., and E. J. Burnham, General Electric Company. (Presented with lantern slides by E. J. Burnham.) Discussion on the above two papers was presented by Messrs. J. Slepian, R. W. Sorensen, D. I. Cone, B. F. Howard and F. W. Peek, Jr., and a written discussion from E. H. Freiburghouse.

Thursday's Technical Session

At the final technical session on Thursday morning, Vice-President Schoolfield presiding, the following papers were presented;

Variable Voltage Equipment for Electric Power Shovels, by R. W. McNeil, Westinghouse Electric & Manufacturing Co. (Presented by the author.) A written discussion was presented from R. S. Stevens.

Temperature of a Contact and Related Current-Interruption Problems, by Joseph Slepian, Westinghouse Electric & Manufacturing Co. (Presented by the author.)

Transcontinental Telephony, by O. B. Jacobs and H. H. Nance, American Telephone and Telegraph Co. (Presented by O. B. Jacobs.)

Controlling Insulation Difficulties in the Vicinity of Great Salt Lake, by B. F. Howard, Mountain States Telephone & Telegraph Co. (Presented with lantern slides by the author.) Discussion by Messrs. J. B. Johnson, K. B. Miller, A. S. Peters, W. C. Lee and B. F. Howard.

Carrier-Current Communication on Submarine Cables, by H. W. Hitchcock, Pacific Telephone and Telegraph Co. (Presented by the author.) Discussion by Messrs. J. E. Heller, K. B. Miller, and W. G. Rubel.

Entertainment Features

On Monday afternoon, practically all the members and guests in attendance participated in an excursion to the Saltair resort on the shores of the Great Salt Lake, where many enjoyed the unique experience of bathing in the lake which is noted for its great buoyancy. Dinner and dancing occupied the time of the visitors until a late hour.
